feasible. With higher spatial resolution, the Raman imaging technique enables the two-dimensional distribution of several chemical composites from the corroded sample to be obtained, and it provides a means of rapidly obtaining surface composition information over a much larger analysis area. It is able to identify the anticrosion effect of the coating on different substrates, and to study and compare the effect of corrosion inhibitors, such as thiourea and benzotriazole on the corrosion of iron surfaces. Two advantages of Raman microscopy are its higher spatial resolution both horizontally and vertically and its ability to record spectra in the low-frequency region. Hence, it is suitable to investigate the pitting corrosion process of metals and alloys involving various oxides and complexes with the chloride ion.

4.4 Biology and Sensor

4.4.1 Biology and Biochemistry

The main purpose of surface Raman spectroscopy to be applied in biological, biochemical and medical systems is to utilize the unique SERS effect with dramatically high sensitivity and molecular (or even chemical bond) selectivity as a powerful analytical tool, which has been well reviewed. There is a good example of SERS study on humic substances adsorbed to noble metal substrates. A variety of SERS substrates have been proposed for studies of humic acid, including Ag sols, Au electrodes, and silver nitrate modified Fe–C–Cr–Ni surfaces. A SERS-active sample has also been prepared in the form of a pellet prepared from an aqueous mixture of humic acid and silver powder. Examples are neurotransmitters, immunoglobulin G, enzymes and amino acids, nucleic acids, eye lens pigments, and intermediate states of rhodopsin. Cytochrome c is a popular protein for SERRS investigations due to its intense heme absorbance and good adsorption characteristics. The orientation of this protein at colloidal Ag surfaces has been investigated under a variety of conditions. Photochemical charge transfer between flavin mononucleotide and a Ag electrode has been investigated by time-resolved SERS. Incorporation of anthracines into lipid monolayers and bilayers has been proposed as a method for investigation of drug transportation through model or biological membranes by measurement of arrival times at the surface. SERS is becoming an increasingly popular method for investigation of drug–nucleic acid interactions, such as binding of acridine drugs to DNA and topoisomerase II, and antitumor drug action within living cancer cells. SERS has been used to identify covalent adducts between another antitumor drug [N(2)-methyl-9-hydroxyellipticinium] and amino acids and nucleic acids. In addition, the structure of adsorbed RNA triple helices has been investigated. It is necessary to emphasize that when SERS or any other surface technique is applied, care should be taken to ensure that the biological molecule keeps its activity and is not denaturalized when adsorbing or bonding at the surface.

4.4.2 Chemical Sensors

Since SERS delivers vibrational spectra of the adsorbed analyte, which are highly specific for the detected substance, SERS has the potential of dual selectivity arising from both adsorption and detection. This can be used for the development of extremely selective sensors with low cross sensitivities or of multi-substance sensors with the identification of individual compounds by their spectra. Since SERS usually uses a metallic substrate for adsorption which will exhibit chemical reactivity and low selectivity, organic modification of the metal surface can solve this problem. Sensors utilizing SERS detection have been developed for a wide range of analytes, including organic molecules in aqueous solutions, nerve agents, and molecules of environmental importance. A SERS-based enzyme-linked sandwich immunoassay has also been developed, whereby the reaction of a peroxidase with o-phenyldiamine and hydrogen peroxide yielded azoaniline which was then detected at a SERS substrate. Subpicogram quantities of the explosive trinitrotoluene have been detected by SERS at colloidal Ag and Au.

4.4.3 Hyphenated Analytical Techniques

Although there are many hyphenated analytical techniques to couple a separate method with IR and Raman spectroscopy, the application of surface IR and surface Raman methods is quite limited and restricted almost to SERS. SERS has been used as a detector for liquid chromatography by flowing a silver hydrosol as the SERS substrate through the chromatography column eluant in a windowless flow cell. The system was optimized with respect to injection time, eluant flow rate, and hydrosol flow rate, and the detection limits for five eluants were determined. Several papers focused on combining SERS with other analytical techniques such as gas chromatography, thin-layer chromatography, and flow injection analysis have appeared. A new gas chromatography detector composed of SERS substrate organic analytes at the surface, and a method for drug analysis by separating a mixture via thin-layer chromatography, followed by SERS detection from the chromatography plate, have been developed.
5 PROSPECTIVE AND FUTURE DEVELOPMENTS

Because of significant developments in materials science, laser and synchrotron technology, and nanotechnology, many opportunities are provided for the fundamental progress for IR spectroscopy and Raman spectroscopy to further enhance our understanding of surface science. The prospects will be given briefly and divided into three parts involving the surfaces, instrumentation and methodology.

5.1 Surfaces

5.1.1 Nanoparticle (Nanorod) Arrays

Enormous enhancements with SEF of up to $10^{14}$ have been found, by which high-quality SERS or SERRS spectra from a single molecule adsorbed on the surface of a single silver particle or aggregated silver colloids can be obtained.$^{29,30}$ It is very interesting to note that only substrate with particle size of 80–100 nm is optimal for SERS. Comparing with the normal SEF of $10^3$, this phenomenon indicates SERS (maybe also SEIRA) substrates with much higher activity can be prepared, in particular with the aid of rapid development of nanofabrication technology. It is very important that the SERS substrate has a very narrow distribution of roughness features, i.e. optimized particle size and shape. Highly ordered periodic arrays of nanodots or nanorods can be prepared by lithography. This technique apparently is a good way to find suitable particle size and shape to generate SERS for various metals. Another approach is to make ordered nanorod arrays as very good SERS-active substrates especially for transition metals (e.g. Ni, Co and Fe); this has been realized in the authors’ laboratory. The arrays are fabricated by electrodepositing metals into the nanoholes of the alumina film as the template.$^{64}$

The SERS intensities depend critically on the length of the rods emerging from the surface. This strategy will be very helpful for obtaining a deeper insight into complicated surface enhancement mechanisms of Raman and IR spectroscopy. The reasonable reproducibility of the regularly structured SERS and SEIRS substrates on a nanometer scale improves the applicability of these sensitive techniques in quantitative chemical analysis and sensors, and also offers the possibility for comparisons with theoretical approaches.

5.1.2 Single Crystal Surfaces and Non-surface-enhanced Raman Scattering Active Surfaces$^{24,65,66}$

Although there have been quite extensive IR studies on atomic flat single crystal surfaces, only a few surface Raman studies have been reported due to its low sensitivity. The early Raman studies were restricted to vacuum–solid and air–solid interfaces. Only recently has a SERS study on true smooth single crystal surfaces been accomplished.$^{8,24,65}$ It should be noted that, at present, there are only a very limited number of molecules with large Raman cross-section that can be used successfully for this investigation. To extend the study to a variety of molecules is one of the major challenges to the further application of surface Raman spectroscopy. The instrumentation needs to be improved and the method needs to be developed including the use of the ATR mode.$^{24}$ Therefore, a detailed and comparative study on both the ordered monocristalline and rough surfaces will achieve a better level of understanding of SERS mechanisms. Moreover, this approach is very helpful for linking the structural properties of in situ electrochemical or catalysis and metal–UHV interfaces, aiding and enriching the structural interpretation of both Raman and IR vibrational data of structural well-defined surfaces.

Starting with Campion’s work in 1982, the development of high quantum efficiency, low noise multichannel detectors and high-throughput spectrometers led to a large increase in the fraction of the Raman signal that can be collected from a given sample. This has enabled several groups to obtain the Raman spectra of nonresonant adsorbates in the monolayer regime on low surface area substrates that do not support SERS. In a recent work by Kagan and McCreery,$^{66}$ the Raman study was extended to some physisorbed molecules on mechanically polished glassy carbon surface at monolayer level with and without the help of resonance Raman effect with reasonable signal-to-noise ratio. This allows insight into both the nature of the adsorbate–substrate interaction and its effect on both the vibrational and electronic properties of the adsorbate.

5.2 Instrumentation

5.2.1 Light Sources$^{26}$

One advantage of surface IR spectroscopy in the mid-IR region over other vibrational techniques such as EELS or neutron scattering arises from its good frequency resolution and over Raman spectroscopy arises from its relatively high sensitivity. However, very few surface IR studies have successfully probed the far-IR region below 400 cm$^{-1}$, mainly because of the difficulty in obtaining high brightness radiation sources operating in this range. Traditional thermal sources tend to run out of energy below 300 cm$^{-1}$, excluding the important region where many adsorbate–substrate vibrations absorb. This effectively precludes direct observation by IR signals of the low wavenumber vibrational modes which have been shown to be important in vibrational energy transfer.
This brightness problem has recently been addressed using synchrotron radiation. The principal advantage of synchrotrons over blackbody sources arises because of their high brightness in a highly collimated beam. It has been shown that the intensity advantage from the use of synchrotron source can exceed that of conventional sources by a factor of 5 at 1000 cm\(^{-1}\), rising to a factor of over 300 at 100 cm\(^{-1}\). This permits spectra to be recorded in the far-IR with signal-to-noise ratios comparable to those obtained in the mid-IR region. Moreover, further development of tunable lasers in various wavelength regions from near-IR to UV will inevitably stimulate wider use of Raman spectroscopy.

5.3 Methods

5.3.1 Surface-enhanced Hyper-Raman Spectroscopy\(^{(67)}\)

Hyper-Raman scattering is a nonlinear three-photon energy conversion process. It offers complementary information to IR Raman spectroscopy and has some advantages over Raman and IR spectroscopies due to its relaxed selection rules. In principle, the hyper-Raman active vibrational modes of a centrosymmetric molecule are complementary to its Raman-active vibrational modes. As a result, compared with its SERS spectrum, the surface-enhanced hyper-Raman (SEHR) spectrum for a centrosymmetric molecule shows some new vibrational bands and significant relative intensity changes. By contrast, the SEHR spectrum for a noncentrosymmetric molecule resembles its SER spectrum with the absence of new vibrational bands. However, the low scattering efficiency has single-handedly impeded the development of hyper-Raman to a prominent analytical technique. For surface species, one has to use surface enhancement to circumvent the low intensity problem. Surface-enhanced hyper-Raman spectroscopy (or scattering) (SEHRS) can greatly increase the surface detection sensitivity with an enhancement factor up to \(10^{10}\). It is possible to obtain rich vibrational information and observe both IR and Raman inactive vibrational modes. Most SEHRS can only obtain signals from adsorbates with large Raman cross-section (such as pyrazine) and dye sample, and most studies were done on colloid surfaces. The aim of research in this area is to find a stable SEHRS substrate with very high activity.

5.3.2 Hyphenated Technique of Raman and Infrared Spectroscopy with Scanning Probe Microscopy\(^{(68)}\)

It is increasingly desirable to couple vibrational data with the corresponding information on surface morphology at microscopic level to probe surface adsorption and reaction sites. There are more than 20 techniques in surface science, including spectroscopies, diffraction techniques and scanning probe microscopy (SPM). Each technique has its own advantages and disadvantages in probing surfaces and interfaces. For instance, spatial resolution for Raman spectroscopy which provides chemical identification falls onto micrometer scale only as mentioned above, while scanning tunneling microscopy has extremely high spatial resolution up to atomic scale but without chemical identification. These two techniques are obviously complementary for probing interfaces for optical and morphological characterization. Several studies have been directed to investigate Ag films and colloids at higher resolution by combining SERS with SPM (STM or AFM) separately. There is no doubt that much useful and reliable information can be obtained if the advantages of these two techniques are used at the same time to study the interface. Thus, a hyphenated Raman/STM system was set-up in the authors’ laboratory after designing the STM head, modifying the Raman optical system, and setting up a new high efficient collection system with the help of fiber optics and proper use of the detection device (Figure 15). Simultaneous STM and Raman measurement has been made on Ag surface and silver island covered highly oriented pyrolytic graphite electrodes to correlate the SERS activity and surface morphology. Further development of a very stable SPM system combined with a highly sensitive Raman system (perhaps an IR system later) makes this technique promising.

5.3.3 Scanning Near-field Optical Microscopy

Another important approach of the hyphenating technique is to develop SNOM that allows optical imaging...
with a spatial resolution (~20 nm) well beyond the
diffraction limit. This technique is described in detail
elsewhere in this Encyclopedia. Combination of SNOM
with Raman spectroscopy will provide a powerful tool
to obtain chemical information of surfaces (interfaces)
with nanometer spatial resolution. Since cross-sections
of Raman scattering are usually extraordinary small,
however, the combination of SNOM and Raman spec-
troscopy will be facilitated by the use of resonance
Raman scattering and SERS. High spatial resolution
SNOM equipment has been developed by using high
efficiency optical fiber probes, and Raman spectra have
been obtained of copper phthalocyanine film with a thick-
ness of about 50 nm on a prism. However, it should
be noted that the sensitivity of this technique is still
quite low compared to the conventional Raman system
due to its extremely low output of laser power. Fur-
ther sophisticated development of the instrumentation
and use of tunable IR lasers, with wavelengths cov-
ering mid-IR and even some far-IR regions, for IR
study are expected to broaden the application of this
method.

ACKNOWLEDGMENTS

This work has been made possible by financial support of
the Natural Science Foundation of China (to Z.Q.T.
and B.R.) and the Ministry of Education of China
(Z.Q.T.). We are grateful to K.Q. Huang, D.Y. Wu,
C.X. She, J.M. Wu and F.M. Liu who have provided
much help and assistance in editing the article. We are
also grateful to B.W. Mao, Y.Y. Liao, C. Li, S.G. Sun,
M.J. Weaver and W.Z. Weng for their valuable comments
and suggestions. Whenever the work from the authors’
group is mentioned in the article, it is the contribution of
self-motivated and hard working students and all other
group members.

Ion scattering spectroscopy (ISS) is used to analyze materials for their atomic constituents for depths from a monolayer to many microns. The probing depth and depth resolution are mainly determined by the energy and mass of the projectile. The projectile energy ranges from several thousand to many million electron-volts. For ISS there are many options for analysis, e.g., scattered incident projectiles, knock-on target atoms, reactants from nuclear reactions between the projectile and target atom, and X-rays from excitation of target atoms by the projectiles. There are also numerous experimental techniques for studying various particular material characteristics, e.g., crystal structure, crystal damage, lattice deformation, and impurity content and location. Each of these areas is addressed, as well as the equipment needed for their implementation. Review articles and books on specific relevant subjects are noted, as well as data analysis techniques and computer analysis and simulation programs.

1 INTRODUCTION

The use of ion beam analysis (IBA) techniques allows the determination of the atomic constituents of a sample (including impurities) as a function of depth and also offers a method to obtain information on the structure of the sample (crystallinity, crystal damage and lattice deformation). The availability of IBA techniques has lead to surface modification techniques and multilayer thin-film structures. IBA techniques also stimulated the development of thin-film deposition techniques and the study of oxidation, reduction and analytical reactions under well-controlled conditions. Although IBA can easily distinguish between depth profile atomic concentrations, chemical bonding effects are generally not observed.

When ions bombard material, the incident particles are scattered or react with the material to give off secondary particles (ions, electrons, etc.) and/or electromagnetic radiation. A fraction of the reacting particles and/or radiation emerge from the sample and a small percentage enters the detector and is detected. Identification of the constituent elements is based on the energy of the emerging particles or radiation, whereas the atomic concentration is derived from the intensity of the emerging particles or radiation.

For IBA the near-surface region is regarded as a bulk region because physical properties generally correspond to those of the bulk material, whereas the outermost atomic layers—the surface—may exhibit significantly different properties from the bulk region.

Section 2 discusses how particles are accelerated and presents examples of the types of accelerators commonly used. Section 3 discusses the various IBA techniques, including their applications. IBA techniques are generally divided into several classes depending on the energy of the beam particles and the type of reaction that the incident energetic ion undergoes. Low-energy ion scattering (LEIS) and secondary ion mass spectrometry (SIMS) use projectiles up to several thousand electron-volts, medium-energy ion scattering (MEIS) includes projectile energies of 10–500 keV and high-energy ion scattering (HEIS) ranges in energy from one to many million electron-volts per atomic mass unit. The latter two energy-range categories include Rutherford backscattering spectroscopy (RBS), elastic recoil detection (ERD), particle-induced X-ray emission (PIXE), and nuclear reaction analysis (NRA). This section (section 3) includes a discussion of the techniques of channeling and blocking that are used in highly structured crystals to determine structural parameters in surfaces and interfaces and the atomic position of impurity atoms. Each of these techniques will be discussed in detail and their major applications given.

Section 4 presents analysis techniques for application of the experimental data and provides references for many of the necessary cross-sections used in the analysis, closing with a brief summary and an indication of future directions.
2 EQUIPMENT

This section is divided into three parts, technically noted by: ionization of an atom, its acceleration and energy selection; scattering of the projectile ion or reaction of the projectile ion with the target nuclei; and energy analysis of the emerging particles and radiation. These three parts will be discussed along with a few ancillary matters. For a more complete discussion of this subject, see Tesner and Nastasi\(^1\) and Chu et al.\(^2\)

2.1 Beam Delivery System

This section is devoted to an explanation of the main types of accelerators used to produce and accelerate charged particles for the study of materials. Charged particles are created in an ion source and can be accelerated to large velocities by passing them through a large potential difference. In order to accomplish this, a high voltage must be produced; Cockcroft and Walton used Greinacher’s idea of multiplying a given voltage by a suitable arrangement of condensers and rectifiers, and in 1932 they built a cascade generator for use in nuclear reaction studies.\(^3\) Cockcroft–Walton-type accelerators are now widely used, especially in ion implanters in the energy range up to 500 kV. Another method to produce high voltages was discovered by van de Graaff in 1931:\(^4\) a fast-moving insulating belt carries charge that is sprayed onto a belt at one electrode and removed at another electrode. In this manner, potentials up to tens of millions of volts can be obtained. The van de Graaff accelerator has become the workhorse for IBA studies in the last few decades and is still used extensively. A modification of this technique has been applied by replacing the insulating belt with an insulating chain. An additional modification has been the creation of the ‘tandem’ accelerator, which initially injects negative ions into a van de Graaff type of accelerator where the high-voltage terminal, positively charged, is in the center of the accelerating column and as the negative ions pass through this high-voltage center one or more electrons are stripped, i.e. removed, in a gas or thin foil to form a positively charged ion that is accelerated further from the positive high-voltage terminal in the center of the accelerator to ground potential. There are two distinct advantages of the tandem accelerator: the ion source is at or near ground potential and allows various kinds of ion sources to be used; and substantially higher energy ions can be obtained because multiply-charged positive ions can be created in the high-voltage region of the tandem accelerator, thereby creating ions with energies much larger than the voltage on the center terminal of the accelerator.

The accelerator types discussed thus far are linear electrostatic accelerators, but there are other types of accelerators that have been used previously. One of these types is a circular accelerator known as a cyclotron,\(^5\) which accelerates ions through a small potential difference many times as they travel in a nearly circular path. Put simply, there are two semicircular electrodes, electrically isolated from each other, with an oscillating voltage applied between the two electrodes. As the ions travel through one semicircular electrode, the voltage between the electrodes is switched and the ions accelerate by twice the applied voltage for each revolution in the cyclotron. The ions follow circular orbits in a homogeneous magnetic field and pass through the alternating voltage many times in order to reach the energy range required for the types of studies considered here.

In most cases the beam leaving the accelerator is not monoenergetic nor necessarily of the same mass. In order to separate the useful beam from the other beam components, either magnetic or electrostatic deflection is used. This deflection usually provides a near-monoenergetic beam of a single mass. Then, the deflected and analyzed beam usually is focused and steered into the scattering chamber and onto the target that is to be analyzed. For a complete description of these aspects, see Tesner and Nastasi\(^1\) and Chu et al.\(^2\)

2.2 Reaction/Scattering Chamber

The reaction chamber contains the material to be analyzed, i.e. the sample, a sample manipulator onto which the sample is mounted and used to position the portion of the sample to be analyzed in front of the incident beam, and detectors to analyze both the mass and the energy of the scattered particles or reactant radiation. In addition, the chamber may have attached to it any necessary equipment to perform ancillary experiments in situ, such as oxidation or diffusion. For a more complete discussion of this subject and papers pertaining to the individual techniques and experiments that are referenced in section 3, see Tesner and Nastasi.\(^1\)

2.3 Scattered Particle and Reactant Radiation Measurement

Electrostatic energy analyzers coupled with a Faraday cup or an electron multiplier are generally used for LEIS systems, whereas solid-state semiconductor detectors are used in higher energy scattering experiments. The electrostatic energy analyzer is of the same construction as the analyzers used in electron spectrometers but with opposite polarities applied to all lens and analyzer elements. In most circumstances the energy resolution (\(\Delta E/E\)) is 0.05–0.5%. The ions are usually measured with a position-sensitive microchannel-plate detector. For more energetic ions, i.e. \(E > 100\) keV, gold barrier silicon
detectors generally are used. These detectors have energy resolutions that vary from about 5 keV to a few tens of keV, depending on many factors, but usually the largest contributing factor is the active area of the detector, with the resolution increasing as the detector area increases. For a complete description of these detectors and others noted later in this contribution, see Knoll.\(^6\)

3 ION BEAM ANALYSIS TECHNIQUES

3.1 Elastic Scattering

3.1.1 Rutherford Backscattering Spectroscopy

The most widely used ion scattering technique for the analysis of surfaces is elastic ion scattering, also known as RBS after Sir Ernest Rutherford’s proposal of the new model for an atom in 1911.\(^7\) Geiger and Marsden\(^8\) performed an experiment to test Rutherford’s theory and unambiguously confirmed the validity of the proposed model. In doing the experiment they came upon a method of analyzing samples. The basic concept of this technique is equivalent to bouncing a billiard ball of one mass off another ball of different mass. If the mass of the projectile ball is less than the mass of the target ball, the projectile ball will bounce backward from the collision with an energy that is dependent on its initial energy, the angle of scattering, and the ratio of the projectile mass to the target atom mass. If the projectile mass is equal to or greater than the target mass, only forward scattering is allowed by the laws of conservation of energy and momentum. A schematic representation of such an elastic collision between a projectile of mass \(m_1\), velocity \(V_0\), initial energy \(E_0\) and final energy \(E_1\), and a target of mass \(m_2\), initially at rest, is shown in Figure 1.

In Figure 1 the scattering angle of the projectile is denoted by \(\theta\) and the recoil angle of the target with respect to the incoming direction of the projectile is denoted by \(\phi\). All quantities are in the laboratory frame of reference. There is a direct correspondence between the energy of the projectile before the collision and after the collision, dependent on the mass of the projectile \(m_1\), the mass of the target, \(m_2\), and the scattering angle \(\theta\). The ratio \(E_1/E_0\) is called the kinematic factor \(K\), and is dependent on \(m_1\), \(m_2\), and \(\theta\), as shown by Equation (1):

\[
K = \frac{(m_1^2 - m_2^2 \sin^2 \theta)^{1/2} + m_1 \cos \theta}{m_1 + m_2} \tag{1}
\]

Thus, if one knows the mass and energy of the projectile, then the mass of the target can be determined if the scattered projectile energy is measured for a particular scattering angle. The probability of a scattering event occurring is directly related to the cross-section for elastic scattering \(\sigma\). More precisely, the differential cross-section \(d\sigma\) is directly proportional to the probability of a scattering event of angle \(\theta\) into a solid angle \(\Omega\). There are two implicit assumptions: that the projectile energy is much greater than the binding energy of the atoms in the target, i.e. of the order of 10 eV; and that the projectile energy is less than the energy for any nuclear reactions or resonances of the incident particles with target nuclei.

The differential elastic scattering cross-section is given by Equation (2):

\[
\sigma(E, \theta) = \frac{1}{N_t} \frac{dQ(E)}{Q} \frac{1}{\Omega(\theta)} \tag{2}
\]

where \(\theta\) is the scattering angle, \(Q\) is the total number of projectile ions, \(dQ\) is the number of projectile ions scattered into the detector that subtends a solid angle \(\Omega\), \(N\) is the volume density of atoms in the target and \(t\) is the target thickness. Therefore, if the differential cross-section, the solid angle subtended by the detector, and the number of scattered projectiles are known, then the areal density, \(N_t\), is determined. For a complete derivation of these equations, see Chu et al.\(^2\)

As the projectiles proceed through the target they encounter many bound electrons that interact with the projectile, causing very small energy loss of the projectile, so that as the projectile penetrates deeper into the target material its energy decreases. The same effect also occurs on the outbound path of the projectile or the reactant nucleus. This leads to an energy loss on both the inbound and outbound paths. From this energy loss and the scattering geometry, the thickness of the target can be determined. A typical RBS spectrum for a 2.0-MeV He\(^{4}\) ion backscattered from a gold film overlayed on a

![Figure 1 Schematic representation of an elastic collision between a projectile of mass \(m_1\), with velocity \(V_0\) and energy \(E_0\) and a target of mass \(m_2\) at rest; \(\theta\) is the scattering angle of the projectile and \(\phi\) is the recoil angle of the target atom.](image-url)
silver film overlayed on a sapphire substrate is shown in Figure 2, where the thickness of each film is determined to be \(10^{14}\) atoms m\(^{-2}\). The high-energy scattering edge is indicated for both Au and Ag. From this spectrum it can be seen that the Au and Ag films have not interdiffused and so it is easy to determine the thickness of each film.

In the geometric arrangement shown in Figure 1, multilayer films may be analyzed as well as interdiffusion between layers. Low-Z impurities are difficult to analyze in this arrangement but can be measured using ERD and NRA.

Because the elastic scattering cross-section is well known from Rutherford’s work,\(^{(5)}\) absolute measurement of individual constituents in a sample can be made if the geometry of the scattering system is known, if measurement of the beam parameters is made and if measurement of the scattered projectile is determined. This applies only if the nuclear scattering event is such that the nuclear potentials of the scattering nuclei do not overlap. The onset of this overlap and its effect on the scattering cross-section are well covered by Tesner and Nastasi.\(^{(1)}\)

Using this technique, depth resolutions of a few tens of nanometers are possible and concentrations of target constituents as low as a few tens of parts-per-million for medium-Z elements and 10 ppm for high-Z elements are possible, although under special conditions smaller depth resolutions and lower concentrations may be obtained. Low-Z (\(Z < 10\)) elements are difficult to measure using this technique but other avenues are available and will be discussed in later sections.

Applications of this technique are commonly used in the study of multilayer film structures, interdiffusion, impurity analysis of medium- and low-Z materials with high-Z impurities, oxidation of materials and accurate determination of stoichiometry.

RBS has, through the years, been divided into subsets defined by the maximum energy of the incident projectile: LEIS (maximum projectile energy = 10 keV), MEIS (50–500 keV), HEIS (many millions of electron-volts per atomic mass unit).

Leis deals with analyzing surface phenomena, where surface means the first atomic layer or two; therefore, it is imperative that the analysis be performed under clean vacuum conditions, i.e. \(10^{-8}\) Pa or better. During analysis the surface being analyzed is changed because the surface is damaged and implantation of the beam occurs; therefore LEIS is normally considered a destructive analysis procedure. Both composition and structure can be determined. LEIS has been used to make direct measurements of interatomic spacings and adsorption sites. Two types of energy analyzers generally are used for these measurements: electrostatic energy analyzers and time-of-flight (TOF) analyzers. Use of the electrostatic analyzer requires the entering particle to be charged, whereas TOF analyzers do not. For a more complete description of the technique and its applications, consult O’Connor and Macdonald,\(^{(9)}\) O’Connor,\(^{(10)}\) Niehus et al,\(^{(11)}\) and Rabalais.\(^{(12)}\)

MEIS and HEIS will be addressed together because the techniques and particle detection are similar. The method is nondestructive and provides elemental composition as a function of depth spanning from the first few tens of atomic layers up to a depth of tens of microns. The main advantages are the short analysis times and the direct and simple manner for analyzing the data. The technique is amenable to simple calibration procedures and yields quantitative results. Mainly inorganic compounds, such as multilayer thin films and bulk samples, are analyzed for composition variation or impurity distribution as a function of depth. The depth resolution typically can be a few tens of nanometers. Biological samples also can be analyzed but they are limited by radiation and thermal damage to the specimen. Elemental identification can be poor for high-Z target material due to small \(\Delta m/m\) differences that lead to small differences in scattered incident beam energy. Also, the sensitivity for light element detection can be limited because of the low scattering cross-section for backscattered beam particles. Interpretation of data can be ambiguous if the sample is not homogeneous.

Alpha particles, He\(^4\), are commonly used as the incident particles, with energies up to a few million electron-volts. Protons are also used for thicker targets because
The stopping power for protons is significantly smaller than for $\text{He}^4$ and the penetration depths are therefore correspondingly greater, but the depth resolution and mass resolution for incident protons is degraded from that of $\text{He}^4$. The spectrum shown in Figure 2 is typical for HEIS. Data analysis programs are available that cannot only analyze experimental data but also predict spectra for specific target configurations.\cite{1,2,13–16}

### 3.1.2 Elastic Recoil Detection

ERD is a technique devised to measure low-$Z$ atoms in medium- to high-$Z$ samples. In this technique the incident beam particles collide with the target and impart a significant fraction of their energy to low-mass atoms in the target; these exit the target and are detected and energy-analyzed. The angle of incidence $\theta$, i.e. the angle of the incoming beam to the target surface normal, is nominally 75° and the scattering angle for detection of the low-$Z$ components of the target, $\phi$, is nominally 30°; see Figure 3 for a representation of the scattering geometry.

These reactions are elastic but are significantly enhanced over the cross-section expected for hard-sphere scattering, i.e. Rutherford scattering. The enhancement is greater than for $\text{He}^4$ and the penetration depths are therefore correspondingly greater, but the nuclear reaction signal is measured easily because it is at a much higher energy. In many cases a thin foil can be used to detect either D or $\text{He}^3$ from the target. For ERD analysis, depth resolution depends on many factors but it is generally larger than for RBS analysis. Excellent discussions of this technique are presented by Tesner and Nastasi\cite{1} and Browning et al.\cite{18}

The peaks shown in Figure 4 result from recoil H and D from the target. For ERD analysis, depth resolution depends on many factors but it is generally larger than for RBS analysis. Excellent discussions of this technique are presented by Tesner and Nastasi\cite{1} and Browning et al.\cite{18}

### 3.2 Inelastic Scattering

#### 3.2.1 Nuclear Reaction Analysis

NRA is based on nuclear reactions that are specific to atomic number and mass. This technique is limited to those elements that exhibit strong nuclear (resonant) reactions and have reactant particles or radiation that can be measured easily. In general, low-$Z$ nuclei, e.g. H, D, T, $\text{He}^3$, $\text{He}^4$, incident on specific isotopes of low- to medium-$Z$ nuclei (up to $Z = 30$) exhibit resonant reactions that are pertinent to this technique. Lists of the relevant reactions have been compiled and can be found in the work by Tesner and Nastasi.\cite{1} It is important to point out that reverse reactions can be used, i.e. not only can the incident beam particles be the low-$Z$ nuclei but they can also be the reactant low- to medium-$Z$ nuclei. A typical reaction is $\text{D(He}_3^+,p)\text{He}^4$ with $Q = 18.352 \text{MeV}$. This reaction can be used to detect either D or $\text{He}^3$. A typical geometrical set-up for this analysis is similar to that shown in Figure 3, with $\theta$ and $\phi$ dependent on the particular reaction used. Figure 5 shows the spectrum for a 1.0-MeV $\text{He}^3$ beam incident on a sample of $\text{ErD}_2$ for an angle of incidence of 15° and a reaction product angle of 15°. The measured count from the $\text{He}^3$ elastically scattered from Er is quite large compared with the count from the nuclear reaction, but the nuclear reaction signal is measured easily because it is at a much higher energy. In many cases a thin foil
the target atom, which allows identification of the atom of the energy difference between two electron states in electrons. The energy for each X-ray is characteristic of inner shells, giving off characteristic X-rays and/or Auger electrons from the outer shells fill the inner electron shells of the target atoms as they traverse a sample. The incident particles create vacancies in the nuclear reactions.

3.2.2 Particle-induced X-ray Emission

An excellent description of the various uses of NRA is given by Tesner and Nastasi, as well as the most useful nuclear reactions.

There are many advantages to this method:

- isotope analysis is easy for those isotopes where nuclear reactions exist;
- there is no natural background;
- Usually the scattered beam particles are well separated from the reaction products.

There are also many drawbacks to the use of this method; the most outstanding are:

- the composition of the target usually cannot be measured during the same analysis;
- the spectra are sometimes difficult to interpret because peaks of different elemental isotopes can overlap;
- the cross-sections are less than for RBS, so much higher beam fluences must be used to obtain comparable counting statistics;
- usually there is no analytical form for the reaction cross-section.

An excellent description of the various uses of NRA is given by Tesner and Nastasi, as well as the most useful nuclear reactions.

3.2.2 Particle-induced X-ray Emission

PIXE uses accelerated particles to ionize the atoms of a sample. The incident particles create vacancies in the inner electron shells of the target atoms as they traverse the target, and the electrons from the outer shells fill the inner shells, giving off characteristic X-rays and/or Auger electrons. The energy for each X-ray is characteristic of the energy difference between two electron states in the target atom, which allows identification of the atom originally ionized, and the specific energy released is called the X-ray line. There are many X-ray lines for each element and the number of X-ray lines per element increases with increasing atomic number. Sample analysis using PIXE is limited almost exclusively to ionization of the K- and L-shells. For excellent discussions on PIXE, see Mayer and Rimini and Munnik.

There are nonaccelerator-based techniques that also analyze materials using induced target X-rays: electron probe microanalysis (EPMA) and X-ray fluorescence (XRF). These two methods are also based on detection of the induced X-rays and only the ionization methods are different from PIXE. These two complementary techniques are covered in other areas of this publication.

For PIXE there are two methods to measure the energy of the X-rays: wavelength-dispersive analysis and energy-dispersive analysis. For the wavelength-dispersive system, X-rays emitted from the sample are reflected from a Bragg crystal and detected using a proportional counter. The angle of scattering determines the energy of the X-rays and the energy resolution is partially determined by the solid angle of the detection system. This technique has superior energy resolution (2–40 eV) for X-ray energies below 20 keV. This analysis technique creates a limitation in that only one X-ray line can be measured for each setting of the Bragg crystal and a small solid angle is necessary for good resolution. These limitations decrease the efficiency of the system. For the energy-dispersive system the X-rays are detected using a solid-state detector, usually a lithium-drifted silicon detector. This system has the advantage that many X-ray lines can be measured using the same setup with a relatively large detection solid angle so that the detection efficiency is high except for low-energy X-rays. The energy resolution for these types of detectors is about 160 eV. For most analyses the advantages of the energy-dispersive system outweigh the advantages of the wavelength-dispersive system.

From the X-ray intensities the amounts of the constituent atoms in the sample can be determined. Analysis of thin samples is relatively easy but for thick targets the analysis is considerably more complicated due to two effects: as the incident particles traverse the target they lose energy through electronic collisions and the ionization cross-section becomes a function of the sample depth; and the X-rays emitted in the sample have an increasing probability of being absorbed in the sample as the depth of X-ray emission increases. These effects are a function not only of depth in the sample but also of the constituent atoms within the sample matrix. Analysis of thick-target PIXE can be complicated; see Munnik.

Sensitivity for PIXE can reach 1 μg g⁻¹ with an absolute detection limit of 10⁻¹⁴ g and it has good sensitivity for elements such as S, P, Cl, K, and Ca. It is this sensitivity...
that gives PIXE its great importance in biological and medical fields.

### 3.3 Channeling and Blocking

The basic idea of both channeling and blocking is best understood if a well-collimated beam of ions is envisaged as incident on a high-symmetry direction of a highly ordered crystal, usually a single crystal. Most of the ions propagate in the large “channels” between the target nuclei and lose only a small fraction of the energy in traversing the crystal compared with the energy that they would lose in traversing an amorphous target or nonaligned crystal. For foreign atoms located in these channels the interaction with the incident ions is very large compared with the native crystal atoms, so there is excellent discrimination even for low concentrations of the foreign atoms. And because the incident beam can be aimed down many different crystal axes, a very accurate measurement of the location of the foreign atom can be made (see, for example, Tesner and Nastasi(1) and Morgan(20)). In addition to the above application, amount and depth distribution of lattice disorder, especially surface disorder, and composition and thickness of amorphous surface layers can be determined.

### 3.4 Miscellaneous

There are three subjects that should be mentioned briefly: analysis with microbeams; external sample analysis; and analysis of polymer films.

For samples that are nonuniform laterally, e.g. grain boundaries, it is necessary to use beams of dimensions as small as 0.25 μm. As beam-focusing components get better, smaller beam dimensions are expected; see Doyle(21) for a complete discussion on the subject and Doyle(22) for applications.

Some types of samples cannot be placed in a vacuum and therefore must be analyzed in air. A technique has been devised to accomplish this analysis, known as external beam analysis (EBA). A review of this technique and some of its applications are given by Doyle et al.(23).

IBA of polymers can be extremely difficult. This subject has been addressed in a review paper by Green and Doyle,(24) which discusses the techniques, problem areas, and areas of application.

### 4 DATA ANALYSIS TECHNIQUES, DATA SOURCES, SUMMARY AND FUTURE DIRECTIONS

There are numerous analysis techniques that apply to very specific applications but there are only two generalized analysis programs that are commonly used for the IBA of experimental data. These two programs also can be used to predict a particular spectrum for known input parameters. The programs are SIM-NRA (Version 4.0) and RUMP (Version 4.0); see Mayer(25) and Doolittle(26) for information on acquiring these programs. There are also data sets available on stopping power, range, and energy-loss partition that are necessary for the analysis programs above; the two most prominent data sets are SRIM-2000 (V.09) and TRIM.SP (see Ziegler et al.(27) and Eckstein,(28) respectively, for information on acquiring these data sets).

This article has dealt with the major aspects in the use of energetic ion beams for the analysis of solid samples, although there are new programs to analyze both liquids and biological samples. Many different approaches have been pointed out for the analysis of sample thickness, composition and state of crystallinity. Specific techniques have been given for the analysis of hydrogen isotopes and isotopes of many other light- to medium-mass elements. Major applications have been given for each technique discussed, and advantages and limitations of the technique have been presented. Data analysis programs have been presented, as well as the data sets needed for the analysis.

The future of IBA appears to grow both in the number of laboratories available for performing IBA and in the number of industries that demonstrate a need for IBA. As existing equipment becomes more sensitive and new equipment comes to market, more techniques are expected to evolve, thereby expanding the breadth and usefulness of IBA.

Photoluminescence in Analysis of Surfaces and Interfaces

Timothy H. Gfroerer
Davidson College, Davidson, USA

1 Introduction

Photoluminescence (PL) is the spontaneous emission of light from a material under optical excitation. The excitation energy and intensity are chosen to probe different regions and excitation concentrations in the sample. PL investigations can be used to characterize a variety of material parameters. PL spectroscopy provides electrical (as opposed to mechanical) characterization, and it is a selective and extremely sensitive probe of discrete electronic states. Features of the emission spectrum can be used to identify surface, interface, and impurity levels and to gauge alloy disorder and interface roughness. The intensity of the PL signal provides information on the quality of surfaces and interfaces. Under pulsed excitation, the transient PL intensity yields the lifetime of nonequilibrium interface and bulk states. Variation of the PL intensity under an applied bias can be used to map the electric field at the surface of a sample. In addition, thermally activated processes cause changes in PL intensity with temperature.

PL analysis is nondestructive. Indeed, the technique requires very little sample manipulation or environmental control. Because the sample is excited optically, electrical contacts and junctions are unnecessary and high-resistivity materials pose no practical difficulty. In addition, time-resolved PL can be very fast, making it useful for characterizing the most rapid processes in a material. The fundamental limitation of PL analysis is its reliance on radiative events. Materials with poor radiative efficiency, such as low-quality indirect bandgap semiconductors, are difficult to study via ordinary PL. Similarly, identification of impurity and defect states depends on their optical activity. Although PL is a very sensitive probe of radiative levels, one must rely on secondary evidence to study states that couple weakly with light.

1 INTRODUCTION

Multilayer material systems are increasingly important in the development of smaller, faster, and more efficient electronic and optoelectronic devices. The primary motivation for using multilayer structures is to change the potential energy of electrons and holes at the material interfaces. Because phenomena at surfaces and interfaces tend to dominate the behavior of excitations in these heterostructures, the performance of many microelectronic devices is limited by the nature of heterojunctions. Smooth and atomically abrupt interfaces are necessary for good optical and electrical reflection, uniform quantum confinement, and high carrier mobility. Even more importantly, defects and impurities at interfaces provide new states for electrons and holes, altering their motion, lifetime, and transition energies.

When light of sufficient energy is incident on a material, photons are absorbed and electronic excitations are created. Eventually, these excitations relax and the electrons return to the ground state. If radiative relaxation occurs, the emitted light is called PL. This light can be collected and analyzed to yield a wealth of information about the photoexcited material. The PL spectrum provides the transition energies, which can be used to determine electronic energy levels. The PL intensity gives a measure of the relative rates of radiative and nonradiative recombination. Variation of the PL intensity with external parameters like temperature and applied voltage can be used to characterize further the underlying electronic states and bands.
PL depends on the nature of the optical excitation. The excitation energy selects the initial photoexcited state and governs the penetration depth of the incident light. The PL signal often depends on the density of photoexcited electrons, and the intensity of the incident beam can be adjusted to control this parameter. When the type or quality of material under investigation varies spatially, the PL signal will change with excitation position. In addition, pulsed optical excitation provides a powerful means for studying transient phenomena. Short laser pulses produce virtually instantaneous excited populations, after which the PL signal can be monitored to determine recombination rates. Because PL often originates near the surface of a material, PL analysis is an important tool in the characterization of surfaces. The utility of PL for this purpose is derived from its unique sensitivity to discrete electronic states, many of which lie near surfaces and interfaces. Using the techniques noted above, the nature of these states can be probed in detail. The energy distribution and density of interface states can be ascertained by studying the excitation intensity dependence of the PL spectrum. The presence of surface adsorbates alters the intensity of the PL signal. When the states serve as long-lived traps, the depth of the trap can be determined by observing thermal activation in temperature-dependent PL. In fact, even if interface states are nonradiative, which is usually the case, the states alter the time-resolved PL of radiative transitions in the material. Nonradiative traps dominate the transient PL signal at low carrier density.

PL is simple, versatile, and nondestructive. The instrumentation that is required for ordinary PL work is modest: an optical source and an optical power meter or spectrophotometer. A typical PL set-up is shown in Figure 1. Because the measurement does not rely on electrical excitation or detection, sample preparation is minimal. This feature makes PL particularly attractive for material systems having poor conductivity or undeveloped contact/junction technology. Measuring the continuous wave PL intensity and spectrum is quick and straightforward. On the other hand, investigating transient PL is more challenging, especially if recombination processes are fast. Instrumentation for time-resolved detection, such as single photon counting, can be expensive and complex. Even so, PL is one of the only techniques available for studying fast transient behavior in materials.

Because PL can be used to study virtually any surface in any environment, it can be used to monitor changes induced by surface modification in real time. For example, unlike most surface characterization techniques, PL is generally not sensitive to the pressure in the sample chamber. Hence, it can be used to study surface properties in relatively high-pressure semiconductor growth reactors. Although PL does depend quite strongly on temperature, liquid helium temperatures being required for the highest spectral resolution, room-temperature measurements are sufficient for many purposes. In addition, PL has little effect on the surface under investigation. Photoinduced changes and sample heating are possible, but low excitation can minimize these effects. In situ PL measurements do require optical access to the sample chamber. Yet, compared with other optical methods of characterization like reflection and absorption, PL is less stringent about beam alignment, surface flatness, and sample thickness.

The advantages of PL analysis listed above derive from the simplicity of optical measurements and the power to probe fundamental electronic properties. The chief drawback of PL analysis also follows from the reliance on optical techniques: the sample under investigation must emit light. Indirect-bandgap semiconductors, where the conduction band minimum is separated from the valence band maximum in momentum space, have inherently low PL efficiency. Nonradiative recombination tends to dominate the relaxation of excited populations in these materials. This problem can be augmented by poor surface quality, where rapid nonradiative events may occur. Nevertheless, once a PL signal is detected, it can be used to characterize both radiative and nonradiative mechanisms. Although it may not be possible to identify directly the nonradiative traps via PL, their signature is evident in several types of PL measurements.

Another shortcoming of PL is the difficulty in estimating the density of interface and impurity states. When these states have radiative levels, they are readily identified in the PL spectrum, and the size of the associated PL peaks provides a relative measure of their presence in the sample. However, measuring the absolute density of these states is a far more formidable task and typically requires an exhaustive analysis of the excitation intensity dependence of the PL signal.

PHOTOLUMINESCENCE IN ANALYSIS OF SURFACES AND INTERFACES

2 PHOTOLUMINESCENCE EXCITATION

The choice of excitation is critical in any PL measurement. The excitation energy and intensity will have profound effects on the PL signal. Although the excitation conditions must be considered carefully, the strength of the PL technique relies heavily on the flexibility that these adjustable parameters provide. Because the absorption of most materials depends on energy, the penetration depth of the incident light will depend on the excitation wavelength. Hence, different excitation energies probe different regions of the sample. The excitation energy also selects the initial excited state in the experiment. Because lasers are monochromatic, intense, and readily focused, they are the instruments of choice for photoluminescence excitation (PLE). For many applications, the excitation energy is not critical. Here, a relatively inexpensive HeNe or diode laser will often satisfy the basic requirement of light exceeding the bandgap energy. In more demanding experiments, the laser is chosen carefully to probe a particular depth or to excite a particular species in the sample.

Unlike the excitation energy, which may or may not be important, the excitation intensity will influence the result of any PL experiment. The excitation intensity controls the density of photoexcited electrons and holes, which governs the behavior of these carriers. Each electron–hole recombination mechanism has a distinct functional dependence on carrier density. For example, the number of interface and impurity states is finite, and recombination at these sites will saturate at high excitation. In addition, the photoexcited carriers themselves can alter the distribution of interface states. Thus, the excitation intensity must be calibrated accurately and controlled precisely.

2.1 Excitation Energy: Penetration Depth and Stoke’s Shift

The absorption of a material depends strongly on the energy of the incident light. In the analysis of surfaces, it is useful to describe this wavelength-dependent absorption by a penetration depth (the inverse of the absorption coefficient), which is a measure of the thickness of the layer that is probed. In direct-bandgap semiconductors, above-bandgap excitation has a penetration depth of the order of 1 μm. The diffusion of photoexcited carriers can vary widely but is typically in the range 1–10 μm. Hence, PL with above-gap excitation is very sensitive to surface effects. In indirect-bandgap semiconductors, or direct-gap semiconductors with sub-bandgap excitation, absorption is weaker and the light penetrates deeper into the sample. Here, the PL is dominated by bulk recombination. If multiple excitation wavelengths are available, this property of PL can be used to distinguish surface and bulk contributions.

Garcia-Garcia et al. have used such an approach to study the surface layer of chemically etched CdTe. When the surface structure is poor, the PL spectrum changes with increasing excitation energy, the strength of defect-related lines increasing relative to bulk features. Correlation of these changes with penetration depth indicates the location of near-surface defects. Furthermore, the authors found that the PL spectrum of a high-quality surface is independent of excitation energy. In an extension of this technique, Wang et al. used the widely divergent penetration of one and two photon absorption processes to distinguish surface and bulk effects. In contrast to relatively slow recombination with two-photon excitation, a fast recombination mechanism dominated the one-photon excitation experiment. This result indicates the presence of rapid recombination sites near the surface of the semiconductor, where the single-photon excitation is absorbed.

Dangling bonds at a semiconductor surface or interface give rise to electronic states within the bandgap. These mid-gap states fill up to the Fermi level with electrons that originate in the bulk of the material. The accumulation of charge at the surface creates an electric field—a depletion region—that leads to bending of the valence and conduction band edges. According to a simple dead-layer model, electron–hole pairs that are generated in this region are swept apart by the electric field, prohibiting radiative recombination. The phenomenon is described quantitatively by a depletion thickness that characterizes this “dead layer”.

Although the dead-layer picture of carrier kinetics at the surface of a semiconductor overlooks the complicated role of surface states in the recombination process, it is useful when PL quenching has an electrostatic origin. For example, Ryswyk and Ellis have studied the effect of I$_2$ on n-GaAs in the context of this model. They used PL depth profiling with multiple excitation wavelengths to determine the depletion thickness in the I$_2$-treated sample. Uosaki et al. have used a similar experimental approach to characterize p-GaAs/electrolyte interfaces. Results were analyzed within the context of the more sophisticated model proposed by Mettler, which accounts for changes in charge separation and surface state recombination. It should be noted that these phenomena are intricately connected, and resolving their contributions to PL quenching is difficult. Although changes in the electric field at the surface should not affect the surface state density, altering the nature or number of surface states can affect depletion and band bending. This point will be discussed in more detail in section 4.
In addition to controlling the penetration depth, the excitation energy selects the initial photoexcited state in the sample. This state is short-lived because thermalization of photoexcited carriers via phonon emission is rapid. Relaxation to within $kT$ of the lowest available states is usually orders of magnitude faster than recombination. Thus, ordinary PL emission only reveals the lowest energy states. Nevertheless, it is possible to obtain spectral information on excited states by collecting the low-energy emission while tuning the excitation energy across higher energy states. The PL signal is enhanced when the excitation energy is resonant with an excited state. The technique, called photoluminescence excitation spectroscopy, is similar to ordinary absorption subject to the condition that there exists a relaxation channel from the excited state to the emission state being monitored. PLE is frequently used to study epilayers on opaque substrates because absorption is not feasible in this case.

Compared to band continua, discrete interface states are relatively sparse. PL is easily dominated by interface states because such states tend to have levels below the intrinsic bands, and carriers are remarkably efficient at finding the lowest available states. However, PLE relies on optical absorption, which is relatively weak for isolated interface sites. Hence, it is usually difficult to uncover interface states in PLE spectra. Nevertheless, PLE has been applied successfully to the characterization of certain surface species. For example, Zhu et al. utilized PLE to identify groups chemisorbed on the surface of TiO$_2$ ultrafine particles.\(^7\) Similarly, Anpo et al. used the dependence of PL on excitation energy to resolve differences between anchored and impregnated Mo/SiO$_2$ catalysts.\(^8\)

An important feature of optical transitions in semiconductor quantum wells (QWs) is the energy difference between the absorption (or PLE) and emission peaks – Stoke’s shift. This shift is a measure of interface fluctuations because it indicates that the thickness of the QW varies with position. Carriers are photoexcited uniformly in the QW but they diffuse to regions of larger well width, where the confinement energy is smaller, before recombining. Deveaud et al. have studied the PL and PLE spectra of a series of multiple QW samples.\(^9\) In samples prepared under optimal growth conditions, they observed two sharp PL peaks, which they attribute to recombination in regions where the QW thickness differs by exactly one atomic monolayer. PLE is used to test whether excitation at the higher energy peak yields emission from the lower energy peak and to confirm that thermalization between the two regions occurs. It has been argued that splittings in PL from QWs like those discussed above can be misleading because impurities can produce similar effects.\(^10\) The ambiguity can be resolved by using PLE where impurity transitions are weak. The structure in PL spectra from QWs will be discussed in more detail in section 3.2.

### 2.2 Excitation Intensity: Interface State Density and Distribution

The intensity of the incident light controls a critical property of the PL experiment: the density of photoexcited electrons and holes. When the carrier density is low, the measurement is dominated by discrete defect and impurity sites at the interfaces and within the bulk of the material. Recombination at these energetically favored sites is frequently referred to as Shockley–Read–Hall (SRH) recombination, in recognition of early work on the statistics of this phenomenon. The SRH rate is proportional to the dominant carrier density $n$. The dominant carrier density is the greater of two quantities: the equilibrium carrier concentration (i.e. the doping level) and the photoexcited carrier concentration. Under intermediate excitation, the discrete states are filled and bulk radiative recombination plays a greater role. Neglecting excitonic effects, these transitions are two-body events between free electrons and holes, so the radiative rate varies as $n^2$. It should be noted that low temperatures or quantum confinement can make Coulomb binding of electron–hole pairs energetically favorable, leading to the formation of excitons that recombine radiatively at a rate proportional to $n$. At the highest carrier densities, three-body Auger recombination becomes important because the rate of this mechanism varies as $n^3$. In the analysis of interfaces, the transition between SRH and radiative recombination is the most important because it depends on the density of defect and impurity sites.

In systems with high interface-to-volume ratios and active layers that are thin relative to the carrier diffusion length, interface effects dominate SRH recombination. In planar structures, the interface-to-volume dependence of SRH recombination can be separated from actual interface phenomena via the interface recombination velocity $S$. The interface recombination rate is defined as $R_i = (S/d)n$, where $d$ is the thickness of the optically active layer. When two interfaces are present, as in a double heterostructure, the two interface contributions are combined: $S$ is replaced by $S_1 + S_2$ (or $2S$ for equivalent interfaces). Because $S$ is independent of carrier density and layer thickness, it can be used to compare interface recombination in a variety of materials. $S$ depends strongly on the nature of the interface. For example, $S$ is of the order of $10^7$ cm$^{-1}$ at the interface of GaAs and air, whereas high-quality GaAs/GaInP interfaces can have $S < 10$ cm$^{-1}$.\(^{11}\)

This reduction of the interface recombination velocity at the edge of a material is called surface passivation.
Because the performance of many optoelectronic devices is limited by interface recombination, interface passivation has been studied extensively. Passivation techniques include epitaxial growth of lattice-matched semiconductor alloys and a variety of chemical surface treatments. Qualitative evaluation of these techniques is straightforward: an increase in the PL signal indicates a decrease in nonradiative interface recombination. Quantitative information on $S$ requires more sophisticated techniques, many of which involve investigations of the excitation intensity dependence of PL.

Komiya et al. measured the excitation-intensity-dependent PL signal from a series of InGaAsP/InP double heterostructures. Although the PL signal was usually linear with excitation power, some samples showed superlinear dependence under intermediate excitation (see Figure 2), indicating a transition between nonradiative and radiative recombination regimes. The lack of such a transition in the other samples suggests that radiative recombination dominated at all excitation levels, which gave an upper limit for $S$. In a very different approach, Mullenborn and Haegel studied single AlGaAs/GaAs and GaInP/GaAs heterostructures where the buried GaAs layer is excited indirectly via either carrier diffusion or recycling (i.e., reabsorption and emission) of photons. The excitation intensity dependence of PL from both layers was used to distinguish between the two mechanisms for carrier generation in the buried layer. Because the two processes are competing, and react differently to interface quality, their relative strengths can be modeled to characterize interface recombination.

The experiments described above combine relative measurements of the PL intensity with considerable assumptions or modeling to obtain quantitative information on semiconductor interfaces. Absolute measurements of the PL intensity provide for a more direct analysis of interfaces. Evaluating the absolute PL intensity requires an estimate of what fraction of the emitted light is collected by the detector. However, the PL emission profile is a complicated function of sample geometry, refraction, internal reflection, and reabsorption. Hence, large uncertainties in this estimate are inevitable. Integrating spheres can be used to ensure that most of the emission is collected, but it is difficult to control environmental parameters such as temperature in these devices.

A very accurate alternative technique for measuring the absolute PL intensity from light-emitting materials with unspecified emission profiles has been developed. The sample can be studied in a controlled environment, and the measurement does not require knowledge of the fraction of emission collected. Determination of the absolute PL intensity relies on the fact that simultaneous relative measurements of radiative and nonradiative recombination can be combined to determine the absolute radiative efficiency (the ratio of photons emitted to photons absorbed). Because the excitation power must be converted into either light or heat, an increase in one must be accompanied by a proportional decrease in the other. The intensity of the emitted light and the temperature change are measured as a function of excitation power to evaluate the relative strength of the radiative and nonradiative mechanisms. Then, extrapolating the temperature change to zero heating, the light signal equivalent to 100% radiative efficiency is obtained.

This technique has been used to measure the absolute radiative efficiency of an InGaAs/InP double heterostructure with an integral substrate reflector. A plot of the normalized light signal vs. temperature change is shown in Figure 3. At low excitation, the relative intensity of the emitted light increases, and the relative temperature change decreases with increasing excitation. However, at high excitation the radiative efficiency rolls off (see Figure 4), and the data begin to show the opposite trend. As predicted by the model described above, the points fall on a straight line and do not depend on whether the efficiency is increasing or decreasing with excitation. Extrapolation to zero heat is not shown in Figure 3 because a false origin is required to give sufficient detail. Nevertheless, the $y$-intercept of the linear fit in Figure 3 can be combined with the excitation and average emission energies to calibrate the relative light signal data. The result of this calibration is presented in Figure 4.

![Figure 2](image-url)  
**Figure 2.** Excitation power dependence of the PL intensity for two different samples. The I-2 PL signal is approximately linear with excitation, whereas the H-1 signal increases superlinearly in the intermediate excitation regime.
The fit in Figure 4 relies on the fact that, in steady state, the rate of carrier generation equals the rate of recombination, as shown in Equation (1):

$$\frac{P_{\text{abs}}}{E_{\text{ex}}} = V \left( \frac{2S}{d} n + \frac{B}{N} n^2 + C n^3 \right)$$

Here, $P_{\text{abs}}$ is the absorbed laser power, $E_{\text{ex}}$ is the laser energy, and $V$ is the volume. The photon recycling factor $N$ is the average number of radiative recombination events required for a photon to escape the semiconductor, and $B$ and $C$ are parameters that describe the rates of radiative and Auger recombination respectively. Because the fit is very sensitive to the coefficients that characterize the different mechanisms for recombination, it can be used to evaluate parameters such as the interface recombination velocity $S$.

Saitoh et al. have argued that the simple picture of an excitation-independent surface recombination velocity is not sufficient to describe the excitation dependence of the PL signal. In particular, when the excitation is intermediate between the SRH and radiative recombination-dominated regimes, the quasi-Fermi levels for electrons and holes split away from the low-excitation pinned position and move toward their respective band edges. The quasi-Fermi levels determine the energy range of surface states that contribute to recombination. Thus, the PL efficiency in this transition region is very sensitive to the density and energy distribution of surface states. The authors have developed an elaborate model of carrier behavior near the surface of the semiconductor that accounts for carrier transport, surface state occupation, band bending, and recombination. Analysis of the excitation-intensity-dependent PL signal in the context of this model is referred to as photoluminescence surface-state spectroscopy (PLS).

The shape of the radiative efficiency curve in the SRH to radiative recombination transition region depends on the distribution of surface states that participate in recombination. If the distribution consists of a discrete set of states with similar energetic positions within the gap, complete saturation of the SRH recombination process will lead to a PL efficiency slope of unity. Efficiency curves with slopes less than unity indicate that the surface-state distribution is continuous and that an increasing number of surface states are participating in recombination as the quasi-Fermi levels move through the bandgap. Hence, variation in the slope of the efficiency curve with
increasing excitation can be used to map the surface-state distribution within the gap. Two distinct surface-state distributions and their corresponding efficiency curves are shown in Figure 5.\(^{16}\) Since its development in 1991, PLS\(^3\) has been applied to a wide number of semiconductor systems. Although some of these studies have uncovered surface states with discrete energies, most have revealed that the surface-state distribution is U-shaped, with increasing density near the band edges.

Excitation-intensity-dependent PL can also be used to study the properties of QWs. Ding et al. measured the excitation intensity \(I_{\text{ex}}\) dependence of the integrated PL signal from asymmetric coupled QWs.\(^{17}\) They note that the PL intensity should vary as \(I_{\text{ex}}^2\) when recombination is dominated by nearly saturated interface traps, but should be proportional to \(I_{\text{ex}}\) when radiative recombination is more important. This behavior was clearly observed in their results. They used the transition intensity to estimate the nonradiative decay time, which suggested that traps were located at the interface of the coupling barrier and the larger well. Excitation-dependent saturation of PL can also be used to determine the relative density of different radiative states. For example, when splittings are observed in the PL from QWs, as described in section 2.1, the lower energy peak often saturates with increasing excitation because of state filling. In this case, the saturation intensity can be used to estimate the size of interface islands in the QW where the lower energy PL is believed to originate.\(^{18}\)

A third application of excitation-intensity-dependent PL is in the evaluation of interface band alignment. Vignaud et al. observed a dramatic excitation-dependent blueshift in the PL from InAlAs/InP heterostructures. They attributed this blueshift to spatially indirect type II transitions across the interface.\(^{19}\) The blueshift is explained as follows: when the conduction band minimum and valence band maximum occur on opposite sides of a semiconductor interface, electrons and holes are trapped in different regions of the heterostructure. Because the electrons and holes are attracted to each other, narrow QWs are formed adjacent to the interface, as shown in Figure 6. As the excitation is increased, carriers accumulate in these wells, increasing the confinement energy of the wells and the dipole energy across the interface. Both of these mechanisms lead to substantial blueshifts in the PL. It is interesting to note that type II transitions, which occur across the interface itself, are especially sensitive to interface quality.

### 3 Photoluminescence Spectrum

Optical transitions provide direct access to the energy level structure of a system. Photons of a particular energy that are absorbed or emitted by a sample provide evidence of electronic states differing by that energy within the material. Absorption is a good probe of the overall band structure of a system because bands have a relatively high density of states. PL emission, on the other hand, tends to favor sparse low-lying states because photoexcited carriers rapidly thermalize through bands and closely spaced states to within \(kT\) of the lowest available levels. This feature of PL makes it particularly effective in the analysis of interfaces where discrete defect and impurity states...
abound. If the state is radiative, it will generate unique peaks in the PL spectrum. Thus, the PL measurement is a very sensitive and selective probe of such states.

In addition to identifying discrete states, PL peak positions can be used to evaluate the composition of semiconductor alloys. Here, the energy of the band-edge emission is correlated with the composition-dependent bandgap of the alloy. This application is also useful in interface analysis where atomic interdiffusion leads to interface alloying. Interface alloys can form narrow wells or barriers that have an impact on the behavior of carriers at heterojunctions. Evidence of interface wells and barriers is often found in the PL spectrum.

Other features of the PL spectrum, including line widths and splittings, provide important information on QW interfaces. These systems are very sensitive to interface roughness because fluctuations as small as one atomic monolayer can alter the carrier confinement energy considerably. When the QW thickness varies substantially within the sampled region, a general broadening of the PL spectrum is observed. In samples with higher quality interfaces, variation in the QW thickness is limited, and recombination in different regions yields sharp, well-resolved peaks in the PL.

### 3.1 Photoluminescence Peak Positions: Energy Levels

In the bulk of a crystalline material, translational symmetry leads to the formation of electronic energy bands. Defects and impurities break the periodicity of the lattice and perturb the band structure locally. The perturbation usually can be characterized by a discrete energy level that lies within the bandgap. Depending on the defect or impurity, the state acts as a donor or acceptor of excess electrons in the crystal. Electrons or holes are attracted to the excess or deficiency of local charge due to the impurity nucleus or defect, and Coulomb binding occurs. The situation can be modeled as a hydrogenic system where the binding energy is reduced by the dielectric constant of the material. Because electrons and holes have different effective masses, donors and acceptors have different binding energies.

When the temperature is sufficiently low, carriers will be trapped at these states. If these carriers recombine radiatively, the energy of the emitted light can be analyzed to determine the energy of the defect or impurity level. Shallow levels, which lie near the conduction or valence band edge, are more likely to participate in radiative recombination, but the sample temperature must be small enough to discourage thermal activation of carriers out of the traps. Deep levels tend to facilitate nonradiative recombination by providing a stop-over for electrons making their way between the conduction and valence bands by emitting phonons. Several intrinsic and impurity transitions are illustrated in Figure 7.

Surfaces and interfaces usually contain a high concentration of impurity and defect states. As the physical termination of the sample, the surface represents a drastic interruption of the material itself. Dangling bonds often provide numerous midgap states that facilitate rapid nonradiative recombination. They also act as getters for ambient impurities. Dangling bonds can be accommodated by a variety of surface treatments and lattice-matching semiconductor epilayers. Even so, impurities accumulate on surfaces before treatment and during growth interruptions. In addition, interface defects due to slight lattice mismatch at semiconductor heterojunctions are inevitable.

In systems where the interfaces and bulk material contribute to the PL, the two components can be distinguished via depth profiling. Thewalt et al. combined PL with spreading resistance analysis (SRA) depth profiling to identify the type and location of several impurities in ultrahigh-purity epitaxial silicon. PL spectra of the substrate and three epitaxial samples are shown in Figure 8. The strong Al line in sample (c) and the weaker line in sample (b) correlate well with an interfacial contaminant detected in SRA. Destructive depth profiling can be accomplished by step-etching and measuring the PL vs. etch depth. Akimoto et al. used this approach to connect specific PL peaks with vacancy complexes at a GaAs/AlGaAs interface.

Some good examples of PL spectral analysis in the characterization of bare surfaces are in the field of semiconductor etching. Reactive ion etching (RIE), where etching is accomplished by bombarding the surface with energetic reactive ions, is an important procedure in the fabrication of optoelectronic devices with submicron features. However, RIE can produce various types of defects in the near-surface region. For optimal device performance, the damage and contamination caused by
RIE should be minimized. PL analysis is very useful in identifying and controlling RIE-induced defects.

Henry et al. used PL to study the effects of various plasmas on exposed surfaces of phosphorus- and boron-doped silicon.\textsuperscript{(22)} As shown in Figure 9, the PL spectrum depended strongly on the plasma composition. Before treatment, the spectrum consisted of a number of lines just below the bandgap that are associated with the boron dopant in the material (B\textsuperscript{TA}, B\textsuperscript{TO}, B\textsubscript{h}, and B\textsuperscript{2TO}). No deep luminescence was observed in the control sample. After treatment, several deep luminescence features emerged in the PL spectrum. The features can be divided into two categories: sharp lines and broad bands. The sharp lines are characteristic of radiative transitions at deep neutral defects in silicon, which are known from other studies involving high-energy particle irradiation. For example, the lines labeled C and G in spectrum 9(b) are recognized as transitions associated with carbon-related defects in silicon. The origin of the broad bands observed in spectra 9(c–e) is not completely understood. It is attributed to recombination at extended defects where the strained silicon lattice creates local potential wells that trap electrons and holes.

Broad, deep PL emission is a common characteristic of damaged semiconductors. Foad et al. have investigated changes in the PL spectrum of ZnTe/GaAs epitaxial layers after RIE and subsequent annealing.\textsuperscript{(23)} RIE leads to a factor of 100 reduction in the near-band-edge emission, accompanied by the appearance of very broad new features well below the gap. One of the low-energy peaks coincides with a specific defect found in bulk ZnTe, but the peak is much broader than observed previously. Upon annealing, near-band-edge PL recovers by one order of magnitude and the deep emission shows more structure, revealing that the very broad, deep emission seen prior to annealing was actually composed of several phonon replicas (transitions assisted by one or more phonons). The annealing results suggest that the strain around RIE-induced defects is reduced.

Deep emission has also been attributed to dislocation networks at the interface of lattice-mismatched heterostructures. The effects of strain and dislocations can be separated in InGaAs/GaAs heterostructures where accommodation of lattice mismatch depends on the InGaAs layer thickness. Strain dominates when the InGaAs is thin, but the strain is relaxed by the formation...
of misfit dislocations when the InGaAs layer exceeds a critical thickness. Joyce et al. observed broad, deep PL in the InGaAs/GaAs system and measured the spectrum as a function of InGaAs thickness.\(^{(24)}\) They found that the intensity of the deep emission increases rapidly above the critical thickness, suggesting that interface dislocations are responsible for the broad, sub-bandgap PL.

As with surface damage, relative changes in surface state and band-edge emission can be used to evaluate surface passivation. For example, Xu et al. have used PL to study the properties of CuSe coatings on CdSe nanocrystals.\(^{(25)}\) The uncoated CdSe nanocrystals produced broad, sub-bandgap PL, which they attributed to recombination at deep surface traps. With increasing CuSe fraction on the CdSe cores, they observed a monotonic decrease in this emission accompanied by steadily increasing band-edge PL. Ordinarily, materials with larger bandgaps are required for surface passivation so that carriers see potential barriers at the interface, shielding them from the surface. Because CuSe has a smaller bandgap than CdSe, surface passivation with this material is unusual. The authors suggest that the CuSe coating is very thin so that the CuSe gap is enhanced by quantum confinement.

Although spectral analysis of sub-bandgap emission is useful for characterizing interfaces, the peak position of the band-edge PL itself provides important information on atomic interdiffusion and interface alloying. The bandgap of a semiconductor alloy depends directly on alloy composition. When heterojunctions are not abrupt, unintentional alloy layers are formed at the interface. Depending on composition, such layers can have bandgaps larger, smaller, or intermediate between the adjoining materials. For example, Guimaraes et al. observed an anomalous emission band below the GaAs and GaInP gaps in GaInP/GaAs heterostructures.\(^{(26)}\) They postulated that the band was due to recombination in GaInPAs intermediate layers, and confirmed their hypothesis by observing an enhancement of the band with an As-rich growth interruption at the interface.

Exchange or accumulation of atomic species at interfaces has a drastic impact on recombination in semiconductor QWs where individual monolayers of material are significant. GaInP/GaAs QW energies reported in the literature vary by as much as 100 meV for well widths below 10 monolayers. Mesrine et al. have shown that this scatter can be explained by two growth-related mechanisms: As/P exchange at interfaces and In surface segregation on GaInP layers.\(^{(27)}\) Limiting cases incorporating a single monolayer of InAs or GaP at an interface more than account for the dispersion in PL energies obtained by different groups.

### 3.2 Photoluminescence Line Width and Splitting: Alloy Disorder and Interface Roughness

Whereas graded interfaces are likely to shift transition energies, interface roughness tends to produce line broadening and splitting in QWs. QW PL peaks are almost always broader than bulk PL. The line broadening is attributed to unintentional variation in the confinement energy in different regions of the well. Two distinct mechanisms contribute to lateral variation in the QW properties: alloy disorder in the well or barrier layers, and interface roughness. When the line width increases rapidly with decreasing well width \(L\), the broadening is usually attributed to interface roughness. The confinement energy depends heavily on \(L\) in narrow wells and, assuming that the scale of interface fluctuations does not depend on layer thickness, decreasing the well width means that the fractional variation in \(L\) is larger. Alloy disorder can also lead to well-width-dependent PL broadening, especially when the disorder is concentrated in the barrier layers. In this case, reducing the well width causes the wavefunction of confined carriers to penetrate deeper into the barriers, thus sampling increasing amounts of disorder.

When optimal growth conditions are achieved, interface fluctuations can be restricted to a single monolayer of atoms and the average lateral extent of atomically smooth interfaces is larger than the wavefunction of the confined state. When PL measurements are conducted at liquid helium temperatures, the confined states are usually Coulomb-bound electron–hole pairs, or excitons. Several possible scenarios for excitons in QWs with single-monolayer fluctuations are shown in Figure 10. Typically, the lateral extent of atomically smooth islands is smaller.

![Figure 10](image_url)

**Figure 10** Models of interface structure relative to the size of the exciton wavefunction: (a) two rough interfaces; (b) one smooth and one rough interface; (c) two smooth interfaces.
than the exciton wavefunction, so the exciton senses a position-dependent distribution of well widths. This phenomenon tends to broaden the PL as excitons recombine in regions with different average well widths. In contrast, when interface island dimensions exceed those of the exciton, most of the recombination occurs within a limited set of QW regions having smooth walls and fixed well width. In this case, discrete lines may be resolved in the QW spectrum.

Because fine structure in low-temperature PL can have many origins, including a variety of impurity transitions, sharp lines in QW spectra must be interpreted with care. Indeed, the growth schedule for the highest quality QWs usually includes growth interruptions at interfaces when excess residual impurities could accumulate. Elman et al. observed splitting in the low-temperature PL of GaAs/AlGaAs QWs, suggesting recombination in well regions differing by one monolayer.\(^{(10)}\) However, the lower energy peak (labeled I in Figure 11) vanished with increasing temperature, showing that it was impurity related. Meanwhile, a third peak at slightly higher energy (labeled \(E_{\text{HH}2}\)) gained strength with temperature, identifying it as an intrinsic QW transition. Thermal activation of carriers out of the relatively sparse impurity-related traps quenched the lower energy peak, whereas thermal population of the higher energy intrinsic state raised its PL to a level comparable with that of the lower intrinsic state.

The measured splitting between the intrinsic peaks was found to equal the energy difference expected for wells differing by one monolayer. The PLE spectrum correlates well with the intrinsic states (the impurity state does not appear) and time-resolved spectra demonstrate that they are coupled, confirming the interpretation that the doublet originates in adjacent QW regions with monolayer-thick deviations. Another expected signature of PL multiplets due to QW regions differing by single monolayers is the increased splitting with confinement energy. Deveaud et al. have compiled experimental results demonstrating this phenomenon.\(^{(9)}\) This group also uses temperature-dependent PL and PLE to confirm that PL peaks are intrinsic and that excitons created in the narrow regions thermalize to the wider zones.

As described above, observation of PL splitting in QWs is unusual because very smooth interfaces are required. In ordinary QWs, PL broadening is more likely. Because broader lines imply a wider distribution of well widths, narrow PL lines generally indicate high-quality QWs. However, this interpretation can be misleading. Ferguson et al. have conducted an experimental and theoretical study of the effects of a misoriented substrate and growth interruption on the variation in QW line width against well thickness \(L\).\(^{(28)}\) In samples with uninterrupted growth, the increase in line width with decreasing \(L\) corresponded to an effective interface roughness of 0.2 monolayers. When growth interruptions are used, the PL line width increased by a factor of 3–4, indicating well-width fluctuations of approximately one monolayer. The increase in line width accompanying growth interruption is attributed to an increase in the lateral extent of interface islands, which is generally regarded as an improvement of the interface. The idea here is that when islands are small the exciton sees a constant average well thickness, but when islands are large the well width depends on exciton position.

In their analysis, Ferguson et al. assumed that the alloy composition of the layers was constant and that the line width reflected interface roughness alone. This interpretation was supported by the strong dependence
of line width on $L$. Woods et al. studied the PL of InGaAsP/InGaAsP QWs and came to the opposite conclusion. Because the line width did not increase in the narrow wells, the broadening was attributed to alloy composition variation in the well and barrier layers. In general, of course, both mechanisms will contribute to the PL line width. For example, Patane et al. found that alloy disorder and interface roughness are required to fit the $L$ dependence of In$_{x}$Ga$_{1-x}$As/GaAs PL lines. Although alloy disorder is sufficient to explain the line width in wide wells, interface roughness is necessary to fit the data at small $L$ (see Figure 12). When $x = 1$, alloy broadening is absent and interface roughness alone must account for the $L$-dependent line width.

**4 PHOTOLUMINESCENCE INTENSITY**

Of all the properties that characterize PL, the intensity of the PL signal has received the most attention in the analysis of interfaces. This interest is due to the fact that, although several important mechanisms affect the PL response, it is generally found that large PL signals correlate with good interface properties. A useful review of the dominant mechanisms and the relationship between them has been provided by Chang et al. In particular, they discuss the roles of the surface recombination velocity $S$ and band bending at the surface in the PL measurement. Because surface recombination is usually nonradiative, and band bending can lead to the formation of a depletion region or “dead layer” where PL is effectively quenched, both of these phenomena tend to reduce the PL intensity. Distinguishing between the two effects is difficult and usually requires a supplementary measurement of the surface potential.

All else being constant, the surface recombination velocity is proportional to the density of surface states. However, changes in the surface-state density can affect the accumulation of charge at the surface, thereby altering the depletion thickness. If increasing the surface-state density enhances the depletion layer, both mechanisms suppress the PL intensity and the surface recombination velocity increases rapidly. Conversely, if the space-charge region is reduced by an increase in the density of surface states, the two mechanisms will have opposite effects on the PL signal and tend to cancel each other out. It should also be noted that, even though changes in surface-state density usually affect band bending, the inverse is not necessarily true. For example, the electric field at the surface can be modified by adsorption of molecules that shift the distribution of electrons between bulk and surface states but leave the surface-state density unchanged. Hence, the coupling of the two phenomena is quite complex.

PL intensity measurements have been used to evaluate a wide variety of surface treatments, including etching, oxidation, hydrogenation, adsorption of gases, deposition of coatings, and heteroepitaxy. The results are usually interpreted within the context of one of the above models: changes in surface-state density or changes in depletion thickness. Occasionally, when supplementary measurements of the surface Fermi level or dependence on applied bias are performed, more sophisticated models that account for both mechanisms are used. Otherwise, restricting the discussion to changes in an effective surface recombination velocity, which contains both effects, can accommodate the ambiguity of the phenomena.

Because a strong PL response is widely regarded as an indicator of a high-quality surface, and PL measurements are nondestructive and environment-insensitive, PL intensity measurements are an important in situ evaluation tool. The PL signal is monitored in real time while the surface is physically or chemically modified. Hence, the advantage of in situ methods is that processing steps can be controlled and optimized precisely. The relative ease of the experiment, combined with the broad implications of results for the optoelectronics industry, has made in situ PL a very popular technique. Indeed, the method has been used to characterize the development of virtually every technologically important surface undergoing almost every technologically relevant process. In these experiments, it is important to bear in mind that PLE itself can induce or accelerate chemical interactions.

As an example, in situ PL has been used to assess InP surfaces during various cleaning and etching steps, oxidation, ambient gas flow, plasma exposure, and
heating.\textsuperscript{31,32} In some cases, laser-induced interactions were found to alter etch rates, surface morphology, and surface contamination.\textsuperscript{32} The results are explained by the availability of photoexcited electrons and holes that catalyze chemical reactions. In situ PL has also been used to probe the passivation of GaAs with heteroepitaxial AlGaAs monolayer by monolayer.\textsuperscript{33} Conducting a similar study outside the growth chamber would have required a long sequence of separate growth runs, where run-to-run scatter in growth conditions could be problematic. Timoshenko et al. have extended the in situ PL technique to evaluate electrochemical treatments of indirect semiconductor surfaces, where pulsed excitation is required to obtain a sufficient PL signal.\textsuperscript{34}

An interesting application of surface-adsorbate-induced changes in PL intensity has been described in a series of publications by Ellis et al.\textsuperscript{35} Molecular species adsorbed onto semiconductor surfaces can be divided into two categories: Lewis acids that have a large electron affinity, and Lewis bases that have a small electron affinity relative to the work function of the material. Lewis acids draw electrons from the bulk to surface electronic states, and Lewis bases push electrons from surface states into the bulk. These shifts in surface charge expand or contract the depletion thickness of the semiconductor, quenching or enhancing the PL intensity. Hence, the partial pressure of a gaseous species that adsorbs to a semiconductor surface can be inferred by monitoring the PL signal, thus forming the basis for a novel chemical sensor.

### 4.1 Dependence on Applied Bias: Surface Potential

As discussed in section 2.1, the accumulation of charge in low-energy states near the surface leads to curvature of the conduction and valence bands. Representative pictures of this phenomenon are shown in Figure 13. If the surface states trap electrons, negative charge collects at the surface and the bands bend upward. If the surface states tend to lose electrons (trap holes), then positive charge accumulates, curving the bands downward. The electric field associated with this space-charge region sweeps electrons and holes in opposite directions, forming a depletion region free of electrons and holes. Because electrons and holes are spatially separated and cannot recombine, the depleted region is referred to as a dead layer. The PL intensity depends on the thickness of the dead layer, which relies on the magnitude of band bending. Increased curvature extends the recombination-free region deeper into the material, quenching the PL signal.

The magnitude of band curvature is characterized by the surface potential $V_s$ indicated in Figure 13. One can compensate for or accentuate the surface potential $V_s$ by applying an external bias to the surface. The resulting change in the depletion thickness can be evaluated by monitoring the PL intensity. Using this approach, surface recombination and band bending contributions to the effective surface recombination velocity can be separated. Indeed, when the external bias exactly cancels the surface potential, the so-called flatband condition is obtained. At flatband, the depletion region is reduced to zero thickness and the intrinsic surface recombination velocity $S_{in}$, excluding dead-layer quenching, can be determined.

For a high-quality surface with a low density of surface states, the dead-layer model alone can explain the dependence of the PL intensity on applied bias. In contrast, when the surface-state density is large, PL quenching is dominated by surface recombination and the dead-layer model does not suffice. Chang et al. have observed both of these scenarios in their study of InP surface treatments.\textsuperscript{31} However, they restrict their interpretation to qualitative statements about the relative role of the two mechanisms in PL extinction.

The difference between the bias-dependent PL signal and the dead-layer fit can be used to make a quantitative estimate of the intrinsic surface recombination velocity. Because the dead-layer model assumes that the intrinsic surface recombination velocity is effectively infinite, it underestimates the PL signal for finite $S_{in}$. Kauffman et al. have used this approach to analyze the excitation intensity dependence of the flatband surface trapping velocity at a GaAs/electrolyte interface.\textsuperscript{36} The excitation intensity dependence of $S_{in}$ is attributed to the filling of surface states. Hence, the analysis distinguishes between carrier trapping and carrier recombination, which occur at very different rates.

Excitation-dependent shifts in the flatband potential itself have been reported also for the GaAs/electrolyte

![Figure 13](image-url)
The nondestructive and environment-insensitive features of PL make this application particularly useful in the evaluation of substrate surfaces, where detection of electrically active features may help to control problems in epitaxial devices. Such features might be overlooked in mechanical investigations of surface morphology. Although the spatial resolution in a PL scanning application is ultimately dictated by surface area and scan time, the diffraction limit of approximately 1 µm can be achieved in the best experimental arrangements. These high-resolution schemes must address carrier diffusion, which can smear images on a much larger scale.

Spatially resolved PL measurements are usually accomplished by scanning the optical excitation spot relative to the sample surface and detecting the PL signal in the far field. One of the first demonstrations of this approach was made by Krawczyk et al. in an investigation of InP surface treatments. By coupling the excitation into one end of an optical fiber and scanning the other end relative to a focusing objective, they achieved resolution of the order of a few microns. They observed wide variation in the PL signal on a microscopic scale. For example, PL images of the effect of annealing on NH4OH-treated InP are shown in Figure 15. The PL topography evolves from a random distribution of depressions and peaks to a flat response with randomly distributed PL islands. The annealing results are attributed to the presence of small oxide islands that protect the surface from thermal degradation.

Scanning the excitation laser with stepping motors or galvanometer mirrors usually requires a few seconds to accumulate a PL image. However, high-speed rastering with resonant mirrors or acousto-optic devices can generate frames at standard video rates. In this case, PL images can be observed in real time. An additional advantage of video-rate laser scanning is the short dwell time (less than 1 µs) at each excitation position, which minimizes the possibility of photodegradation.

Although spatially resolved PL usually focuses on the band edge or integrated PL signal, spectral selectivity can be incorporated to map the distribution of particular surface states. Tajima has used this approach to plot the deep-level distribution in the near-surface region of GaAs and Si wafers. Because these states tend to saturate at high excitation, he emphasizes the importance of using a low laser power and stabilizing the system mechanically to accommodate long dwell times. He also points out that the surface finish must be controlled carefully to avoid surface-treatment-related phenomena like those discussed above.

The spatial dependence of the PL spectrum itself can be used to evaluate uniformity of alloy composition, epilayer thickness, and a variety of other material properties that affect PL spectra. For example, the PL spectrum has

4.2 Spatial Dependence: Interface Uniformity and Carrier Diffusion

Because PL intensity is an indicator of interface quality, measurements of the PL signal vs. position provide information on the spatial uniformity of interface properties.
PHOTOLUMINESCENCE IN ANALYSIS OF SURFACES AND INTERFACES

Figure 15 PL images of InP treated with NH₄OH: (a) as treated; (b) annealed at 350 °C; (c) annealed at 450 °C. The PL intensity scale in (b) and (c) is 10 times smaller than in (a).

been recorded as a function of position to look for signs of dislocations or residual stress in laterally overgrown InP on InP-coated Si substrates. Dislocations are expected to reduce the PL signal, and stress tends to shift and broaden PL peaks. Hence, the spatially resolved InP/Si PL was compared with that of lattice-matched InP layers grown homoepitaxially on InP substrates. The measured PL peak was as strong and narrow as that of the homoepitaxial InP with little shift in peak wavelength, suggesting that the overgrowth layer was dislocation and stress free. In addition, the PL spectrum was independent of position, indicating good uniformity in layer quality.

When a laser is focused on a surface, the minimum spot size is determined by the diffraction limit, which is approximately equivalent to the wavelength of the laser light. In the analysis of semiconductors, the optical excitation energy must exceed the bandgap, which usually corresponds to wavelengths in the visible or near-infrared. Hence, the diffraction-limited spot size is of the order of 1 μm. In the absence of carrier diffusion, the excitation spot size governs the spatial resolution of PL measurements. However, photogenerated carriers often diffuse average distances much larger than 1 μm before recombining, so the PL is generated in a broader region than the original excitation spot. Restricting the PL collection can circumvent diffusion-limited spatial resolution.

The most straightforward approach to this problem is a PL extension of confocal microscopy. Using matched illumination and collection optics with back focal plane apertures, enhanced spatial resolution, improved depth profiling, and insensitivity to scattered light are obtained. Only light originating in the focal spot is imaged by the collection optics. In the context of PL experiments, the configuration rejects luminescence due to recombination of carriers outside the illuminated area. A typical experimental set-up is shown in Figure 16. Fong et al. have used confocal PL to study a GaAs/AlGaAs QW grown on a grooved substrate. The improved spatial resolution permitted them to profile abrupt fluctuations (on a scale of 1 μm) in alloy composition and QW thickness. In the confocal measurement, if the detection

Figure 16 Typical experimental set-up for confocal PL measurements.
aperture is translated laterally in the image plane, the corresponding detection spot can be maneuvered relative to the excitation spot. This technique can be used to monitor the diffusion process itself. For example, Hubner et al. have measured the diffusion length along semiconductor quantum wire structures.\textsuperscript{143} A variation in carrier transport with wire width is explained by changes in sidewall recombination due to different surface-to-volume ratios.

Finally, it should be pointed out that the diffraction limit itself can be surmounted when optical measurements are made in the near-field. If a subwavelength aperture is positioned in the near-field region of the optical emission, resolution comparable to the aperture size can be obtained. The most straightforward manifestation of this idea is to place a mask with a tiny hole very close to the sample surface such that excitation and PL must pass through the aperture. A more popular technique known as near-field scanning optical microscopy utilizes the tip of an extruded optical fiber to excite and/or collect the PL emission. Both of these approaches have produced spatial resolution of the order of 100 nm. Yet, with emission areas this small, generating sufficient PL signal under appropriate excitation conditions can be quite challenging.

### 4.3 Time Dependence: Recombination Rates

When CW excitation is used in a PL experiment, the system quickly converges on steady state. The rate of excitation equals the rate of recombination, and the photogenerated carrier density is constant in time. In contrast, when a material is excited by a series of short laser pulses, the concentration of carriers depends strongly on time. Because the laser pulse can be much shorter than the average recombination time, a specific carrier density can be generated almost instantaneously. The photoexcited carriers then recombine at a rate that is characteristic of the recombination path they follow. Time-resolved PL measurements can be used to determine carrier lifetimes, and to identify and characterize various recombination mechanisms in the material.

Photogenerated carrier lifetimes are obtained by monitoring the transient PL signal after pulsed excitation. Although the experimental apparatus required to make such a measurement depends on the desired resolution, the most common detection scheme is time-correlated single photon counting. When a photon is incident on a photodetector, an electrical pulse is generated. This pulse and an excitation reference pulse are fed into a constant fraction discriminator, which is designed to create output pulses that are timed correctly independent of input pulse size. Next, the signal and reference pulses are sent to a time-to-amplitude converter. This device uses the two input pulses as start and stop triggers for a linearly charged timing capacitor and produces an output pulse whose amplitude is governed by the capacitor charge. Thus, the output pulse height is proportional to the delay between input pulses. The output pulses are sorted according to amplitude and counted by a multichannel analyzer, yielding the transient PL decay.

As discussed in section 2.2, there are three general mechanisms for recombination in semiconductors: SRH transitions via intermediate states, radiative events, and Auger scattering. Equation (1) can be rewritten in terms of the nonequilibrium carrier lifetime $\tau$ as shown in Equation (2):

$$\frac{1}{\tau} = \frac{2S}{d} + \frac{B}{N} n^2 + C n^2$$  \hspace{1cm} (2)

It is important to recall that this expression relies on two assumptions: SRH recombination is dominated by interface phenomena and two equivalent interfaces are present in the system. In the analysis of interfaces, we are primarily interested in the SRH term, and in the carrier-density-dependent transition from SRH to bulk recombination. As the excitation level is increased, radiative transitions usually become important well before Auger scattering must be considered. Hence, the Auger term in Equation (2) can be ignored for our purposes. It should be noted, however, that it is possible for low-quality small-bandgap semiconductors with large $C$ coefficients to have Auger rates comparable to the radiative rate when interface recombination begins to saturate.

Neglecting this possibility and assuming that the intrinsic carrier concentration is small, we can identify two important regimes in the carrier kinetics. At low excitation, the carriers are dilute and radiative recombination, which is proportional to $n$, is weak. Hence, the lifetime $\tau \approx d/2S$ is independent of excitation intensity. In this regime, measurements of $\tau$ vs. the active layer thickness $d$ provide direct access to the interface recombination velocity. At the opposite extreme, when interface states are saturated and the radiative rate is fast, $1/\tau \approx (B/N)n$ and the lifetime decreases with increasing excitation. In this context, it is important to realize that $n$ is not constant in time-resolved PL measurements. Rather, it decreases steadily after pulsed excitation via recombination processes. Therefore, at this excitation level one often observes both of the above phenomena in the transient PL signal: fast $n$-dependent decay at early times is followed by a slow, exponential SRH component. Some representative decay curves for GaAs/AlGaAs double heterostructures of varying thickness are shown in Figure 17.\textsuperscript{44}
Quantitative analysis of such nonexponential multi-component decay curves is difficult. The situation is simplified in the case of doped materials with relatively high equilibrium carrier concentrations. Here, the photoexcitation can be kept well below the doping level so that the fixed majority carrier density controls the recombination kinetics. Because $n$ is essentially constant throughout the transient measurement, the lifetime is independent of excitation even in the radiative and Auger regimes. Lifetimes in a set of samples covering a wide range of doping concentrations can yield accurate recombination coefficients. In particular, a discrete transition from $n$-independent lifetimes to steadily decreasing $n$-dependent lifetimes should be observed when the carrier concentration reaches the threshold for significant bulk contributions.

Returning to the intrinsic (low equilibrium carrier concentration) case, if the pulsed excitation is kept sufficiently weak then even the initial photoexcited carrier density is within the SRH regime. Thus, an exponential PL decay with a constant lifetime is expected. As described above, the variation in $\tau$ with layer thickness yields the interface recombination velocity $S$. An excellent example of this type of experiment is the investigation by Domen et al. of Zn doping in AlGaInP/GaInP double heterostructures. Zinc was intentionally incorporated into the upper cladding layer and the resulting carrier lifetime in the active layer was evaluated via time-resolved PL. Measured lifetimes for different doping concentrations are plotted against active layer thickness in Figure 18. The results show the expected behavior ($1/\tau \propto 1/d$) when separated into three regimes that are distinguished by the size of the active layer relative to the Zn-diffused region. In region I, only the top interface is degraded by the presence of Zn. In region II, an increasing fraction of the active layer suffers from diffused Zn. In region III, the high-concentration Zn penetrates all the way through the thin active layer and attacks the bottom cladding interface. The recombination velocities at the relevant interfaces are quickly obtained from the slope of the linear fits.

Time-resolved PL can also be used to distinguish between surface-state and depletion-layer contributions to PL quenching. A decrease in the integrated PL signal implies that the nonradiative recombination rate is enhanced relative to the radiative rate. Such an enhancement can be attributed to one of two mechanisms: an increase in the density of interface states, or an increase in the dead layer thickness. In transient PL, accelerated non-radiative recombination is manifested as a decrease in the photoexcited carrier lifetime. For example, wet-etch surface modification of GaInP has been characterized by CW and time-resolved PL. Etchants yielding enhanced CW PL signals produced corresponding increases in carrier.

Figure 17 PL decay curves for a set of GaAs/AlGaAs double heterostructures and an $n^+/n^-/n^+$ GaAs homostructure. Active layer thickness (µm) and carrier lifetime (ns) are indicated in the plot (lifetimes are obtained by fitting the exponential tail of the curves).

Figure 18 Recombination rate vs. the reciprocal of the active layer thickness in Zn-doped AlGaInP/GaInP double heterostructures. Symbols representing different doping levels are specified in the plot.
lifetime, indicating that the nonradiative recombination rate is effectively reduced.

In this particular experiment, it is not clear whether the etching procedure removes nonradiative recombination sites or depletion-inducing surface charge. This shortcoming in the interpretation can be addressed by conducting the transient PL measurements at high excitation, where photoexcited carriers screen the electric field in the space-charge region. If the injection level is sufficiently high, the bands are essentially flat at the surface and changes in the carrier lifetime can be unambiguously attributed to changes in the surface-state density. Lunt et al. have demonstrated this approach in a comprehensive investigation of GaAs surfaces exposed to a variety of sulfur, nitrogen, and oxygen donors. Some treatments produced an increase in the flatband carrier lifetime, indicating a decrease in the intrinsic surface recombination velocity. Meanwhile, other reagents produced substantial increases in the steady-state PL signal but did not affect the high-injection recombination rate. In this case, the results suggest that the enhanced PL is primarily due to changes in the equilibrium band bending. Thus, the two phenomena are effectively separated.

One final application of transient PL to note is the identification of transitions involving type II band alignment. Because these transitions occur between electrons and holes that are separated in real space (see Figure 6), the electron–hole wavefunction overlap is small. Thus, type II optical transitions are expected to proceed more slowly than transitions in type I systems.

4.4 Temperature Dependence: Thermal Population

When light is incident on a semiconductor, photoexcitation of electrons from the valence to conduction band can occur for any photon energy exceeding the bandgap. In this process, the difference between the excitation energy and the bandgap goes into the kinetic energy of the photoexcited carriers. Thus, the initial distribution of electron and hole energies depends on energy conservation, not temperature, and the original carrier populations are nonthermal. For example, if the excitation energy is much larger than the bandgap, the electrons and holes will be created high in their respective bands with kinetic energies far exceeding the characteristic thermal energy of the lattice $kT$. The electrons and holes then thermalize with the lattice by emitting phonons and, in the absence of Fermi filling effects, settle into Boltzmann distributions above their respective band edges. Because this process almost always occurs on a timescale much faster than that of recombination, thermal distributions are usually observed in ordinary PL. Thus, in PL experiments, temperature is primarily used to tune the thermal occupation of available states.

At the lowest temperatures, PL is dominated by the lowest energy levels. For instance, excitons (electrons and holes bound by the Coulomb interaction) and shallow impurity traps often appear in low-temperature PL. These states are characterized by binding energies of the order of a few milli-electron-volts, which is small relative to $kT$ at ordinary temperatures. As the sample temperature and corresponding thermal energy are increased, excitons dissociate and carriers vacate shallow traps, reducing the intensity of these features in the PL spectrum. It is important to note here that the PL signal from any level depends on two parameters: the fractional population, and the density of participating states. Thus, relatively sparse low-energy traps appear in low-temperature PL because the thermal population of high-density band levels is very small. However, when the thermal population of band levels is appreciable, band transitions dominate the PL because of the abundance of states taking part.

In addition to the population of discrete states, thermal distributions are manifested in the PL line width of band-edge transitions. When $kT$ exceeds the inhomogeneous broadening in the sample, a high-energy Boltzmann tail appears on the PL peak. This feature can be useful for estimating the local temperature of the sample. However, because thermal quenching can hide sparse low-energy states and thermal broadening can obscure important details in the spectrum, certain PL experiments must be conducted at relatively low (i.e. liquid helium) temperatures.

Relative changes in state population with temperature provide evidence that PL peaks originate in the same part of the sample and that carriers are free to move between the available states. As discussed in section 3.2, multiple peaks in the PL of high-quality QWs are frequently attributed to states in regions of the well differing by single monolayers. In these systems, thermal redistribution among states rules out an important competing explanation: the peaks being due to recombination in separate regions of the sample where carriers do not mix. The temperature-dependent PL spectra in Figure 11 clearly show thermal redistribution among states. The peak labeled $E_{\text{HH2}}$ gains strength with increasing temperature, as expected for thermal population of a higher energy state. In contrast, the peak labeled $I$ vanishes at high temperature, demonstrating the importance of the other parameter that controls PL intensity – the density of states. Peak $I$ is strong at low temperature because carriers are trapped at these sites and do not have enough thermal energy to escape, but it disappears at high temperature because the states are sparse relative to the intrinsic bands.

In the characterization of discrete low-energy states, quantitative analysis of the decrease in PL intensity with
energy increases. In contrast, nonradiative recombination is a condition that decreases in likelihood as the average momentum of carriers must have equal and opposite momenta, which is much smaller than that for excitons. In this case, recombination is dominated by processes that involve thermally activated multiphonon events.

A good example of this behavior is the single- and two-photon excitation studies of ZnSe conducted by Wang et al. As discussed in section 2.1, single-photon above-gap excitation is absorbed very close to the surface, whereas two-photon excitation penetrates deep into the bulk. In the single-photon excitation experiments, the transient PL reveals short carrier lifetimes that diminish with increasing temperature, as expected for nonradiative surface recombination. In contrast, relatively long lifetimes are observed under two-photon excitation and the lifetime is extended at higher temperatures, indicating that radiative transitions dominate in the bulk.

5 PHOTOLUMINESCENCE POLARIZATION

Polarization is another important degree of freedom in optical measurements. In PL experiments, the emission polarization depends on the orientation of the dipole oscillator. Ordinarily, all orientations of electron–hole pair recombination events are equally probable, so the PL is not polarized. However, a variation in PL intensity with electric field orientation is sometimes observed. The maxima and minima in the polarization-angle-dependent PL signal usually occur for electric fields aligned with crystallographic axes. Polarization anisotropy in PL can be attributed to bond asymmetries, alloy composition modulation, and strain.

Investigations of PL polarization in the analysis of interfaces are relatively sparse. Nevertheless, they can be quite useful for identifying qualitative features of interfaces. Vignaud et al. observed large polarization anisotropy in the PL from InAlAs/InP heterostructures. They found that the polarization angle yielding the maximum PL signal depended on the specific interface structure. When a thin well of InAs was present at the interface, the PL signal peaked with the polarizer parallel to the [011] axis. On the contrary, when a thin InAlP barrier was present, the PL signal was strongest along [011]. Although the exact origin of this phenomenon was not fully understood, the two scenarios agreed with other measurements that distinguished between the two types of interfaces. The polarization anisotropy was tentatively attributed to local interface bond asymmetry.

Another system that has displayed marked PL polarization anisotropy is ZnCdSe/ZnSe QWs grown on GaAs(110) surfaces. The variation in PL intensity with polarization angle for one such QW is shown in Figure 20. The ratio of maximum to minimum polarized PL signals can be calculated using Luttinger parameters, processes tend to accelerate with increasing temperature. In particular, nonradiative interface recombination usually involves thermally activated multiphonon events. 

![Figure 19 Arrhenius plots of the temperature-dependent PL intensity from ZnSe/CdSe submonolayer QWs. Deposition times of 1 s, 2 s, and 4 s, as indicated in the plot, correspond to well thicknesses of 1/4, 1/2, and 1 monolayer, respectively.](image-url)
which describe the valence band dispersion in the semiconductor. Assuming that the Luttinger parameters of ZnCdSe are similar to those of ZnSe, the calculated ratio is much smaller than that found experimentally. The enhanced polarization anisotropy in this system is attributed to compressive strain in the well layer. This interpretation is consistent with the observation of a very narrow PL line width in this sample. Because the lattice mismatch is accommodated by uniform strain rather than dislocations at the interface, the distribution of states in the QW should be relatively sharp.

6 CONCLUSION

PL analysis is a powerful tool in the characterization of surfaces and interfaces. Although a number of experimental techniques can provide detailed mechanical information about interfaces, the optoelectronics industry that drives most interface investigations is ultimately concerned with optical and electronic properties. Mechanical information is useful because it is closely correlated with these properties, but PL measurements explore electronic features directly. Other techniques can provide similar access, but they typically require more sophisticated excitation or detection schemes.

PLE is simple, but it is also quite versatile. The excitation energy and optical intensity can be chosen to study different regions and recombination mechanisms near interfaces. Because absorption of the incident light depends on the excitation energy, this parameter determines the depth of the PL probe. Using PLE, absorption and emission energies are observed simultaneously to evaluate the distribution of electronic states. The excitation intensity is even more important, controlling the density of photoexcited electrons. This density is critical in the interpretation of recombination dynamics.

The PL signal itself is characterized by three essential features: energy, intensity, and polarization. Because PL is the result of optical transitions between electronic states, the PL spectrum gives precise information on the energy levels available to electrons in the material. The intensity of the PL signal depends on the rate of radiative and nonradiative events, which depends in turn on the density of nonradiative interface states. Although investigations of PL polarization are still relatively sparse and are not well understood, they can identify unique anisotropic features in the underlying crystal. Future work in this area should lead to a more complete picture of asymmetry at surfaces and interfaces.

PL measurements are not sensitive to the pressure in the sample chamber and can be performed at virtually any temperature. These features make PL an excellent in situ probe of surface or interface modification. Even so, variation of the PL signal with external parameters such as temperature and applied bias can provide additional information on the nature of interfaces. Temperature-dependent thermal activation of electronic states can be used to estimate their depth below the intrinsic bands. An applied bias shifts the bands at the surface, permitting evaluation of the zero-bias band bending. Thus, the availability of PL under a wide variety of experimental conditions provides for advanced measurement opportunities.

Applications of PL analysis range from simple spatial scans of epitaxial wafers to exhaustive investigations of excitation-intensity-dependent PL in novel materials. Furthermore, new PL techniques continue to emerge, expanding the arsenal of PL analysis. Because PLE is usually absorbed near the surface, and interfaces tend to dominate electronic behavior in layered systems, PL is especially well suited to surface and interface investigations. Interfaces are increasingly important in new optoelectronic materials where layered structures are becoming thinner and more complex. Thus, although PL measurements have been useful for the characterization and refinement of such materials, they can be expected to play an even greater role in the future.

If the distance dependence of a particular type of interaction is strong, the distance control based on that interaction is very sensitive to small changes in tip–sample separation. By scanning the probe tip over the sample surface while keeping the interaction strength constant using a feedback loop, the surface contours can be followed by the tip with high accuracy. By monitoring the vertical position of the tip as a function of the lateral position, a three-dimensional image of the sample surface is obtained. The motion of the tip both laterally and vertically with respect to the sample surface can be realized with subatomic accuracy by means of piezoelectric drives.

In contrast to electron microscopy and vacuum-based surface analytical methods, proximal probe techniques can be operated in air and in liquids in addition to in vacuum. Therefore, proximal probe techniques offer great potential for investigations of solid–liquid interfaces or for in vivo investigations of biological specimens. Furthermore, proximal probe techniques can be operated in a wide temperature range (from millikelvin up to more than 1000 K) and under extreme conditions (e.g. in high magnetic fields or high-pressure conditions). The most attractive feature of proximal probe techniques is, however, that they combine ultrahigh spatial resolution (down to the atomic scale) with high-resolution spectroscopic measurements so that detailed information about the physical, chemical or biological state of the sample can be extracted. Limiting factors are the finite size and often ill-defined state of the probe tips and the limited information depth of proximal probe techniques. It has also been found to be difficult to identify elemental species based solely on proximal probe measurements although chemical-selective imaging even down to the atomic scale is nowadays routinely achieved.

1 INTRODUCTION

Scanning tunneling microscopy (STM) was the first proximal probe technique to be developed. It is based on vacuum tunneling of electrons between an electrically conducting probe tip and an electrically conducting sample. The schematic set-up for an STM experiment is shown in Figure 1. An atomically sharp tip is brought within a distance of only a few ångströms (1 Å = 0.1 nm = 10⁻¹⁰ m) from the sample surface by means of a piezoelectric drive. If a bias voltage U has been applied between tip and sample, a tunneling current I will flow due to the quantum mechanical tunneling effect even before mechanical point contact is reached. Since the tunneling current is strongly (exponentially) dependent on the tip–surface separation, it can be used very efficiently for distance control. By scanning the tip
over the sample surface while keeping the tunneling current constant, the surface contours can be traced by the tip. A "constant-current topograph" is finally gained by monitoring the vertical position \(z\) of the tip as a function of lateral position \((x, y)\) which is again controlled by piezoelectric drives. Besides its use to control the tip–surface separation, the tunneling current contains valuable information about the local electronic properties of the sample surface.

Alternatively, different probes, e.g. a sharp optical probe, may be brought within close proximity to the sample at a distance \(s\) which is smaller than the optical wavelength \(\lambda\) used. In this so-called near-field regime the spatial resolution, which can be achieved, is no longer limited by diffraction, but rather by geometric parameters: the distance \(s\) between the probe tip and the sample surface and the effective radius of curvature \(R\) of the probe tip. In addition to the achievement of super-resolution beyond the diffraction limit, scanning near-field optical microscopy (SNOM) provides valuable information about local optical properties. Various optical contrast mechanisms may be exploited, similarly to conventional optical microscopy.

Another type of proximal probe technique, scanning force microscopy (SFM), has found extremely wide fields of application. In SFM, the forces or force gradients acting between a sharp tip, mounted on a cantilever, and a sample are detected by the bending of the cantilever. Depending on the particular type of SFM operation, with the tip and sample either in contact or not, short-range (e.g. ion–ion repulsion) or long-range [e.g. van der Waals (VDW), electrostatic, magnetic] forces, respectively, can be measured. SFM can be applied to any sample, including insulators, and can be combined with STM or SNOM operation by using appropriate probe tips. It also constitutes the basic set-up for various other proximal probe techniques, such as scanning near-field acoustic microscopy, scanning near-field thermal microscopy, scanning capacitance microscopy (SCM) and scanning ion conductance microscopy.

2 TUNNELING MICROSCOPY-BASED TECHNIQUES

2.1 Theory and Methods

In this section, the basic principles of STM will be outlined and section 3 will focus on various modes of STM operation for chemical-specific imaging.

STM is based on the quantum-mechanical tunnel effect. A simple one-dimensional model is depicted in Figure 2. An electron of energy \(E\) is approaching a potential barrier of height \(V_0\) and width \(s\) from the left. Even if we assume that \(V_0 > E\), there exists a finite probability for the electron to traverse the potential barrier due to its quantum-mechanical wave nature. If the barrier is sufficiently high and wide \((ks \gg 1)\), then this probability is given by Equation (1):

\[
T = \frac{16k^2e^2}{(k^2 + \kappa^2)^2} e^{-2\kappa s}
\]

Various optical contrast mechanisms may be exploited, similarly to conventional optical microscopy.
where (Equation 2)
\[ k = \frac{\sqrt{2mE}}{\hbar} \]  
and (Equation 3)
\[ \kappa = \frac{\sqrt{2m(V_0 - E)}}{\hbar} \]  
with \( m \) being the electron mass and \( \hbar \) Planck’s constant divided by 2\( \pi \).

The dominant contribution to the transmission coefficient \( T \) comes from the factor \( \exp(-2k \bar{s}) \). This strong exponential dependence of \( T \) on the barrier width \( \bar{s} \) and the square root of the effective barrier height \( (V_0 - E) \) is typical for tunneling, independent of the exact shape of the barrier. Changing the barrier width by only 1 Å typically leads to a change of the barrier transmission by one order of magnitude.

In the three-dimensional case to be considered for describing the STM geometry correctly, a perturbative treatment of tunneling, as introduced by Bardeen,\(^8\) provides an appropriate insight into the physics of the tunneling process as well as a connection to specific tip and sample surface properties. Within Bardeen’s transfer Hamiltonian approach, the tunneling current can be evaluated in first-order time-dependent perturbation theory according to Equation (4):
\[ I = \frac{2\pi e}{h} \sum_{\mu, \nu} \left[ f(E_\mu)[1 - f(E_\nu + eU)] - f(E_\nu + eU) \right] \times \left[ 1 - f(E_\nu) \right] |M_{\mu \nu}|^2 \delta(E_\nu - E_F) \]

where \( f(E) \) is the Fermi function, \( U \) is the applied sample bias voltage, \( M_{\mu \nu} \) is the tunneling matrix element between the unperturbed electronic states \( \psi_\mu \) of the tip and \( \psi_\nu \) of the sample and \( E_\mu(E_\nu) \) is the energy of the state \( \psi_\mu(\psi_\nu) \) in the absence of tunneling. The delta function describes the conservation of energy for the case of elastic tunneling. The tunneling matrix element is given by Equation (5):
\[ M_{\mu \nu} = \frac{-\hbar^2}{2m} \int dS (\psi_\mu^* \nabla \psi_\nu - \psi_\nu^* \nabla \psi_\mu) \]

where the integral has to be evaluated over an arbitrary surface lying entirely within the vacuum barrier region separating tip and sample. To derive the matrix element \( M_{\mu \nu} \) from Equation (5), explicit expressions for the wave functions \( \psi_\mu \) and \( \psi_\nu \) of the tip and sample, respectively, are required, but \( \psi_\mu \) is normally not known. Tersoff and Hamann,\(^9,10\) who first applied the transfer Hamiltonian approach to STM, used the simplest possible model for the tip with spherical symmetry. In this model, the tunneling matrix element is evaluated for an \( s \)-type tip wave function \( \psi_\mu \), whereas contributions from tip wave functions with orbital quantum number \( 1 \neq 0 \) have been neglected. Within this \( s \)-wave tip model the tunneling current in the limits of low temperature and small applied bias voltage becomes (Equation 6):
\[ I \propto U n_s(E_F) \exp(2\pi R) \sum_v |\psi_v(r_0)|^2 \delta(E_v - E_F) \]

where \( n_s(E_F) \) is the density of states at the Fermi level of the tip, \( R \) is the effective tip radius and \( r_0 \) is the center of curvature of the tip. The quantity (Equation 7)
\[ n_s(E_F, r_0) = \sum_v |\psi_v(r_0)|^2 \delta(E_v - E_F) \]

can be identified with the surface local density of states (LDOS) at the Fermi level \( (E_F) \), i.e. the charge density from electronic states at \( E_F \) of the sample, evaluated at the center of curvature \( r_0 \) of the effective tip. The STM images obtained at low bias in the constant current mode therefore represent contour maps of constant surface LDOS at \( E_F \) evaluated at the center of curvature of the effective tip, provided that the \( s \)-wave approximation for the tip can be justified. Since the wave functions decay exponentially in the \( z \)-direction normal to the surface (Equation 8):
\[ |\psi_v(r)| \propto \exp(-\kappa z) \]

it follows that (Equation 9)
\[ |\psi_v(r_0)|^2 \propto \exp[-2\kappa(s + R)] \]

where \( s \) denotes the distance between the sample surface and the front end of the tip. Therefore, the tunneling current, given by Equation (6), becomes exponentially dependent on the distance \( s \) (Equation 10):
\[ I \propto \exp(-2\kappa s) \]

similarly to the case of a one-dimensional tunnel barrier (see Equation 1). Unfortunately, the simple interpretation of constant current STM images as given by Tersoff and Hamann is no longer valid for tip wave functions with angular dependence or for high applied bias voltages. Since STM tips are usually made from tungsten or platinum–iridium alloy wires for which the density of states at the Fermi level is dominated by \( d \)-states rather than by \( s \)-states,\(^11\) the evaluation of the tunneling current according to the Equations (4) and (5) requires the calculation of the tunneling matrix element for tip wave functions with angular dependence \( (1 \neq 0) \). Chen\(^12\) has shown that generally the tunneling matrix element can simply be obtained from a “derivative rule”: the angle dependence of the tip wave function in terms of \( x \) and \( y \) and...
where the derivatives have to act on the sample surface wave function at the center of the apex atom. For instance, the tunneling matrix element for a $p_z$-tip state is proportional to the $z$-derivative of the sample surface wave function at the center of the apex atom at $r_0$.

In terms of a microscopic view of the STM imaging mechanism,(13) illustrated in Figure 3, a dangling-bond state at the tip apex atom is scanned over a two-dimensional array of atomic-like states at the sample surface. Overlap of the tip state with the atomic-like states on the sample surface generates a tunneling conductance which depends on the relative position of the tip state and the sample state. The atomic corrugation $\Delta z$ depends on the spatial distribution in addition to the symmetry of tip and sample surface states. Generally, for non-$s$-wave tip states, the tip apex atom follows a contour, determined by the derivatives of the sample surface wave functions, which exhibit much stronger corrugation than the contour of constant surface LDOS at $E_F$.

Next, we consider effects due to the finite size of the applied bias voltage. First, the bias determines the energy window of those electronic states which can contribute to the tunneling current. Second, a finite bias and the corresponding electric field ($\sim 10^8$ V m$^{-1}$) can lead to a distortion of the tip and sample surface wave functions, $\psi_t$ and $\psi_s$, and also to a modification of the energy eigenvalues $E_t$ and $E_s$. The derivation of these distorted tip and sample surface wave functions and energy eigenvalues under the presence of an applied bias is, however, a difficult problem. Therefore, as a first approximation, the undistorted zero-voltage wave functions and energy eigenvalues are usually taken. Consequently, the effect of a finite bias $U$ only enters through an energy offset $\Delta E = eU$ of the undistorted surface wave functions or density of states relative to the tip states. Under this assumption, Equation (14) for the tunneling current as a generalization of the result of Tersoff and Hamann may be used:

$$I \propto eU \int_0^{eU} n_t(\pm eU \mp \varepsilon)n_s(\varepsilon)T(s, \varepsilon, eU)\,d\varepsilon$$  \hspace{1cm} (14)

with an energy- and bias-dependent transmission coefficient $T(s, \varepsilon, eU)$ given by Equation (15):

$$T(s, \varepsilon, eU) = \exp \left\{ -2(s + R) \right\} \times \frac{2m}{h^2} \left( \frac{\phi_t + \phi_s}{2} + \frac{eU}{2} - \varepsilon \right)^{1/2}$$  \hspace{1cm} (15)

where $\phi_t(\phi_s)$ denotes the tip (sample surface) work function and $\varepsilon = E - E_F$ is the energy measured with respect to the Fermi level of the sample. By writing Equations (14) and (15), matrix element effects in tunneling are expressed in terms of a modified decay rate $k$ including a dependence on energy and applied bias voltage.

The experimental investigation of the bias dependence allows the extraction of various spectroscopic information at high spatial resolution, ultimately down to the atomic level. The spectroscopic capability of STM combined with its ultrahigh spatial resolution is its most powerful feature and makes it the most outstanding proximal probe technique for basic science studies. Figures 4(a–d) show a simplified one-dimensional potential energy diagram at zero temperature for the system consisting of the tip (left electrode) and the sample (right electrode) which are separated by a small vacuum gap. For zero applied bias (Figure 4b) the Fermi levels of tip and sample are equal at equilibrium. If a bias voltage $U$ is applied to the sample, the main consequence is a rigid shift of the energy levels downward or upward in energy by an amount $|eU|$, depending on whether the polarity is positive (Figure 4c) or negative (Figure 4d). For positive sample bias, the net tunneling current arises from electrons that tunnel from the occupied states of the tip into unoccupied states of the sample (Figure 4c), whereas at negative sample bias, electrons tunnel from occupied states of the sample into unoccupied states of the tip. Consequently, the bias polarity determines

---

**Figure 3** Microscopic view of the STM imaging mechanism which can be described by a process of bond forming and bond breaking between atomic-like tip and sample surface states.
whether unoccupied or occupied sample electronic states are probed.

By varying the amount of the applied bias voltage, one can select the electronic states that contribute to the tunneling current and, in principle, measure the LDOS. For instance, the current increases strongly if the applied bias voltage allows the onset of tunneling into a maximum of the unoccupied sample electronic density of states. Therefore, the first derivative of the current–voltage characteristic, $I(U)/U$, should reflect the electronic density of states to a first approximation. By differentiation of Equation (14) one obtains Equation (16): 

$$ \frac{dI}{dU}(U) \propto n_t(0)n_s(eU)T(s, eU, eU) + eU \frac{d}{dU}[n_t(\pm eU \mp \varepsilon)]n_s(\varepsilon)T(s, \varepsilon, eU) d\varepsilon + eU \frac{d}{dU}n_t(\pm eU \mp \varepsilon)n_s(\varepsilon)T(s, \varepsilon, eU) d\varepsilon \quad (16) $$

If we assume that the electronic density of states for the tip is featureless in the energy window determined by the applied bias, i.e. $dn_t/dU \approx 0$, then we can neglect the second term in Equation (16). Furthermore, at a fixed location the increase of the transmission coefficient with the applied bias voltage is smooth and monotonic. Therefore, structure in the $dI/dU(U)$ curve can usually be attributed to structure in the state density $n_s$ via the first term in Equation (16). Under these assumptions we can write Equation (17):

$$ \frac{dI}{dU}(U) \propto n_s(eU)T(s, eU, eU) \quad (17) $$

with

$$ T(s, eU, eU) = \exp \left( -2(s + R) \right) \times \frac{2m}{\hbar^2} \left( \frac{\phi_t + \phi_s}{2} - \frac{eU}{2} \right)^{1/2} \quad (18) $$

Figure 4 Energy level diagrams for tip (T) and sample (s). (a) Independent tip and sample; (b) tip and sample at equilibrium, separated by a small vacuum gap; (c) positive sample bias, electrons tunnel from the tip to the sample; (d) negative sample bias, electrons tunnel from the sample into the tip.
The dominant contribution to the tunneling conductance comes from electrons near the Fermi level of the negatively biased electrode because the transmission coefficient becomes maximum in this case (Equation 19):

\[
T_{\text{max}}(s, eU, eU) = \exp\left(-2(s + R) \right) \times \frac{2m}{\hbar^2} \left( \frac{\phi_t + \phi_s}{2} - \frac{|eU|}{2} \right)^{1/2}
\]

This fact has been indicated in Figures 4(b) and (c) by arrows of differing size.

As an important consequence of the dominant contribution of tunneling from states near the Fermi level of the negatively biased electrode, tunneling from the tip to the sample (Figure 4c) mainly probes the sample’s empty states with negligible influence of the tip’s occupied states. On the other hand, tunneling from the sample to the tip is much more sensitive to the electronic structure of the tip’s empty states which sometimes prevents detailed spectroscopic STM studies of the sample’s occupied states.\(^{(15)}\)

STM can nowadays provide atomic or molecular resolution on many different kinds of materials routinely. On the other hand, the analytical capabilities of STM are not yet fully developed. The determination of chemical species by STM or tunneling spectroscopy is inherently prevented by the fact that valence electronic states accessible by the STM cannot unequivocally be related with a particular element in a multicomponent solid. However, considerable progress has been made in recent years to exploit various contrast mechanisms to differentiate between different atomic or molecular species. In the following, several examples of chemical contrast mechanisms in STM will be presented and discussed.

### 2.2 Scanning Tunneling Spectroscopy of Dangling Bonds, Surface States and Image States

Scanning tunneling spectroscopy (STS) can be a powerful experimental method for atom-selective imaging, as first demonstrated at the example of compound semiconductors such as GaAs.\(^{(16)}\) Charge transfer from Ga to As results in an occupied electronic state centered at the As sites and an empty state centered at the Ga sites. Consequently, bias-polarity-dependent STM images selectively show the As atoms at negative sample bias and the Ga atoms at positive sample bias. A similar atom-selective imaging mechanism is found for other III–V semiconductor compounds.

Another example is given by the Si(111)–(\(\sqrt{3} \times \sqrt{3}\))Al system.\(^{(17,18)}\) STM images of this surface obtained at positive sample bias reveal the (\(\sqrt{3} \times \sqrt{3}\)) lattice together with defect sites which appear less bright (Figure 5a). At negative sample bias, the contrast reverses (Figure 5b). Based on the observed dependence of the defect density on Al coverage, it was concluded that the bright protrusions seen at positive bias must correspond to Al adatoms, whereas the defect sites were attributed to Si adatoms substituting for Al in the (\(\sqrt{3} \times \sqrt{3}\)) structure below an Al coverage of one-third of a monolayer. The Si adatoms give rise to an extra dangling-bond defect state near −0.4 eV, which causes the Si adatoms to appear brighter than the Al adatoms for negative sample bias. Based on the polarity-dependent contrast, an atom-selective imaging can be achieved for the Si(111)–(\(\sqrt{3} \times \sqrt{3}\))Al system (similar to that for the GaAs(110) surface). For the general case of an arbitrary multicomponent solid, however, the details of charge transfer between different atomic species are usually not known and therefore an assignment of “topographic” features in STM images to particular atomic species cannot be made without additional information about the system.

Alternatively, the spectroscopic capabilities of STM have been exploited to differentiate between different chemical species in multicomponent metal systems based on characteristic features in the local tunneling spectra arising, e.g., from surface states, surface resonances or adsorbate-induced states. An example is presented in Figures 6(a–c) showing a submonolayer Fe film grown at room temperature on a stepped W(110) substrate.\(^{(19,20)}\) The topography (Figure 6a) is dominated by iron islands of monolayer height and a lateral extent of about 5 nm, although a small amount of the deposited material tends to decorate the monoatomic steps of the W.
substrate. A distinction between Fe and W is difficult to make based on such constant-current topographs, particularly close to step edges where the difference in the apparent topographic height between Fe and W almost vanishes. Therefore, chemical-specific fingerprints are needed which can be extracted from the local tunneling spectra measured either above the bare W(110) substrate (Figure 6b, spectrum A) or above the Fe islands (Figure 6b, spectrum B). While the $dI/dU - U$ characteristic measured above the Fe islands exhibits a pronounced peak centered at $U = +0.2 \text{ V}$ corresponding to an empty d-state, the spectrum measured above the bare W(110) substrate shows no significant feature in this bias voltage regime. Based on the pronounced difference between the tunneling spectra measured above Fe and W, a chemical-specific imaging of the ultrathin film system can be achieved by spatially resolved measurements of the differential tunneling conductivity $dI/dU (x, y)$ for selected values of the applied dc bias voltage. This is demonstrated in Figure 6(c), which shows a map of $dI/dU (x, y)$ where the applied bias voltage was changed every 80 scan lines in steps of $\Delta U = 0.2 \text{ V}$. At
$U = +0.2$ V (Figure 6c, top part) the Fe islands appear bright compared to the W substrate corresponding to the high differential tunneling conductivity of Fe at $U = +0.2$ V as known from the local tunneling spectrum (Figure 6b, curve B). On the other hand, at $U = +1.0$ V (Figure 6c, bottom part) the Fe islands appear dark compared with the W substrate, which is explained by the much lower differential tunneling conductivity of Fe compared with W for high sample bias voltage (Figure 6b). Accordingly, a contrast flip in the $dI/dU(x, y)$ image (Figure 6c) is observed between $U = +0.2$ and +1.0 V, corresponding to the crossing point of the two local tunneling spectra presented in Figure 6(b). To obtain high chemical contrast in the $dI/dU(x, y)$ map, it is therefore important to select an appropriate dc bias voltage for which the difference in the differential tunneling conductivity between different chemical species appears to be the highest. This information can easily be extracted from local $dI/dU–U$ spectra as demonstrated for the Fe/W(110) system in the present case.

The method for chemical-selective imaging of multicomponent metal surfaces at the nanometer scale outlined above is applicable quite generally. It is known that most metal surfaces exhibit some pronounced density-of-states feature within the bias voltage regime accessible by STM. Other examples include Gd(0001),$^{21,22}$ or Fe(001)$^{23,24}$ and Cr(001)$^{25}$ for which pronounced d-like electronic states close to the Fermi level have been observed by tunneling spectroscopy. As an important application, the formation of a Cr–Fe alloy could be studied at the atomic level (Figures 7a and b), resulting from the growth of submonolayer Cr on Fe(001) at elevated temperatures ($290 \degree$ C)$^{25}$.

One of the limitations in the application of tunneling spectroscopy to chemical-selective imaging based on pronounced density-of-states features of the sample surface is given by occasionally strong effects of tip states on the spectroscopic results, particularly with regard to the occupied-state density probed at negative sample bias voltages.$^{15}$ On the other hand, special tip states obtained, e.g. by an adsorbate at the front end of the tip, can sometimes be very useful for chemical-selective imaging at the atomic level. This was first demonstrated by a direct observation of surface chemical order on a Pt$_{25}$Ni$_{75}$(111) surface$^{26}$ based on a difference in apparent topographic height between Pt and Ni atoms of 0.3 Å as seen under special tunneling conditions (Figure 8). It was proposed that an adsorbate on the tip can explain the chemically resolved images at extremely low bias voltage because an adsorbate, such as oxygen, may tend to form a chemical bond more likely with one element (in this case Ni) than with the other (Pt), leading to the conclusion that the bright species in Figure 8 are Ni atoms. A similar discrimination between different elements based on a special tip state was also demonstrated for several other metal alloy systems$^{27,28}$ and for oxygen-induced reconstructions of Cu and Ni surfaces.$^{29,30}$
Chemical contrast on metal surfaces can also be achieved via spectroscopic STM studies of image states. Image states can provide even higher elemental contrast than do surface states because they are narrower and have a higher amplitude. Figures 9(a) and (b) show an example of submonolayer Cu on W(110). The Cu stripes grown at the W(110) substrate steps cannot be distinguished in the topographic STM image. However, they clearly show up if the sample bias voltage is tuned to an image-state resonance of Cu. The difference picture subtracts out the topography and provides an elemental map of the surface. Since the image state positions are depending on the surface work function, the contrast obtained reflects the magnitude of the work function difference between the different elemental species.

2.3 Local Work Function Mapping

Instead of using image-state resonances which require high bias voltages \( U > 5 \text{ V} \) leading to an increase in tip–surface separation and therefore to a reduced spatial resolution, it is also possible to map out local work function variations by measuring the spatially resolved local tunneling barrier height \( \phi \). Motivated by Equation (10), \( I \propto \exp(-2ks) \), with (Equation 20)

\[
\kappa = \frac{\sqrt{2m(V_0 - E)}}{h}
\]

for a rectangular potential barrier of effective height \( (V_0 - E) \), a local barrier height \( \phi \) can be introduced in the general case by Equation (21):

\[
\phi \propto \frac{\hbar^2}{8m} \left( \frac{d \ln I}{ds} \right)^2
\]

Consequently, by modulating the tip–surface separation \( s \) by \( ds \) while scanning at a constant average tunneling current \( I \), the modulation of the \( \ln I \) signal provides a direct measure of the local barrier height. For a large tip–surface separation, the local barrier height reflects the surface local work function \( \phi_s \), which has a chemical component.
determined by the chemical nature and structure of the solid only, in addition to an electrical component determined by the chemical nature of the solid and its surface crystallographic orientation. Therefore, spatially resolved measurements of $\phi$ can be used to map chemical inhomogeneities at surfaces [Figures 10(a) and (b)] and also different crystallographic facets of small crystallites.\(^{35}\)

On the atomic scale, it is more appropriate to relate the measured local barrier height with the decay rates of the wave functions describing the sample surface and the tip. Lateral variations of $\phi$ then have to be interpreted as lateral variations in the decay rate of the surface wave function. Figure 11 shows an example of different atomic-scale superstructures of Gd on W(110) at submonolayer coverage. The atomic-scale variation of the measured local barrier height reflects the atomic-scale variations of the surface wave-functions whereas the spatial dependence of the average value of the measured barrier height reflects the difference in the local work function for the different types of superstructures.\(^{36}\)

### 2.4 Thermovoltage Mapping

Another contrast mechanism which has been exploited for chemical mapping is based on the thermovoltage across the tunneling barrier which is built up if a temperature difference between tip and sample exists.\(^{37}\) In case of different Fermi distributions of tip and sample, a net thermally driven current will result even for zero bias according to Equation (4). However, if the external current is zero, an electric charge is induced associated with a bias voltage leading to a tunneling current which is opposed to the thermally driven current. At equilibrium the two cancel exactly. However, spatial variations of the electronic structure may modify the balance which is responsible for the finite measured thermovoltage across the vacuum barrier. To first approximation the
thermovoltage $U_{\text{th}}$ is given by Equation (22):\(^{(37)}\)

\[U_{\text{th}} = \frac{2\kappa^2 e}{\hbar} (T^2 - T_s^2) \left[ \ln n_1 \right]' + \left[ \ln n_s \right]' + \frac{s}{\hbar} \left( \frac{2m}{\Phi} \right)^{1/2}\]

(22)

where $k_B$ is Boltzmann’s constant, $T_t$ and $T_s$ are the temperatures of tip and sample and $s$ is the tip–sample separation. The first and second terms in Equation (22) contributing to the thermovoltage are determined by the logarithmic derivatives of the electronic density of states of tip and sample whereas the third term depends on the tip–sample distance and the local work function $\Phi$.

As an example, the early stages of growth of Ag on Au(111) have been studied by thermovoltage imaging. Figures 12(a) and (b) show the topography (a) and the simultaneously obtained thermovoltage map of submonolayer Ag on the Au substrate (b). Based on the topographic image it cannot be determined to what extent the Au substrate is covered by Ag. On the other hand, the thermovoltage map provides a clear contrast between the two different elements with the Au substrate appearing bright (thermovoltage of $-25 \mu V$). Obviously, some Ag has diffused towards the step edges of the Au(111) substrate which is hardly seen in the topographic image.

### 2.5 Spin-polarized Scanning Tunneling Spectroscopy

So far, we have considered the dependence of the tunneling current on the tip–sample separation $s$, the sample bias voltage $U$, and the local barrier height $\Phi$. However, we have not yet considered the spin of the tunneling electrons and the additional spin dependence of the tunneling current if magnetic electrodes are involved (Equation 23):

\[I = I(s, U, \Phi, \uparrow)\]

(23)

By exploiting the spin dependence of the tunneling current, magnetic contrast down to the atomic level can be achieved.\(^{(38-40)}\)

In the case of two ferromagnetic electrodes for which the directions of the internal magnetic fields differ by an angle $\theta$, it can be shown within a free-electron model and in the limit of small applied bias voltage that the tunneling conductance $\sigma$ is given by Equation (24):\(^{(38)}\)

\[\sigma = \sigma_{\text{ref}} (1 + P_{\text{FB}} \cdot P_{\text{FB}} \cos \theta)\]

(24)

where, $P_{\text{FB}}$ and $P_{\text{FB}}$ denote the effective spin polarizations of the ferromagnet–barrier interfaces and $\sigma_{\text{ref}}$ is a mean conductance which is proportional to $\exp(-2ks)$. It is easily verified that the effective polarization for the whole tunnel junction introduced by Equation (25):

\[P_{\text{FB}} := P_{\text{FB}} \cdot P_{\text{FB}}\]

(25)

becomes Equation (26):

\[P_{\text{FB}} = \frac{\sigma_{\uparrow\uparrow} - \sigma_{\uparrow\downarrow}}{\sigma_{\uparrow\uparrow} + \sigma_{\uparrow\downarrow}}\]

(26)

where $\sigma_{\uparrow\uparrow}$ and $\sigma_{\uparrow\downarrow}$ denote the tunneling conductances in the case of parallel ($\theta = 0^\circ$) and antiparallel ($\theta = 180^\circ$) alignment of the internal magnetic field directions, respectively. Spin-polarized scanning tunneling microscopy
(SPSTM) performed with ferromagnetic probe tips on magnetic samples allows the mapping of spatial variations of the effective spin polarization of the tunnel junction as well as spatially resolved studies of the spin-resolved electronic density of states of the sample surface provided that the spin-resolved electronic density of states of the probe tip is known (at least in the energy window relevant for tunneling). SPSTM even allows the discrimination between different magnetic ions at the atomic scale.\textsuperscript{39,40} This was first demonstrated by the example of Fe\textsubscript{3}O\textsubscript{4} (magnetite) for which the Fe\textsuperscript{2+} and Fe\textsuperscript{3+} sites in the (001) plane of octahedrally coordinated Fe sites of Fe\textsubscript{3}O\textsubscript{4} could be distinguished by using a ferromagnetic Fe probe tip [Figures 13(a) and (b)]. Since SPSTM is sensitive to the surface magnetization rather than the magnetic stray field, as for magnetic force microscopy,\textsuperscript{7} it can even be applied to antiferromagnetic samples.\textsuperscript{41} Another important application of SPSTM is the observation of magnetic domains and domain walls on a nanometer scale, as was first demonstrated for ultrathin Gd films.\textsuperscript{42} In this case, spin-polarized vacuum tunneling into an exchange split surface state allowed a clear separation of topographic, electronic and magnetic structure information.

2.6 Inelastic Electron Tunneling Spectroscopy

In addition to elastic tunneling processes, in which the energy of the tunneling electrons is conserved, electrons may also tunnel inelastically due to interactions with elementary excitations such as molecular vibrations or collective lattice vibrations (phonons), as schematically depicted in Figures 14(a–d).

For molecular species IETS\textsuperscript{43,44} combined with STM might become a powerful technique to identify functional groups. A first experiment toward this goal was performed with sorbic acid adsorbed on graphite.\textsuperscript{45} A series of strong peaks was observed in the tunneling spectrum with the energetic positions of the peaks corresponding approximately to the vibrational modes of the molecule. In another experiment,\textsuperscript{46–48} IETS traces of an isolated acetylene (C\textsubscript{2}H\textsubscript{2}) molecule adsorbed on a Cu(100) surface showed an increase in tunneling conductance at an energy corresponding to the excitation of the C–H stretch mode [Figures 15(a) and (b)]. Additionally, an isotopic shift was observed for deuterated acetylene (C\textsubscript{2}D\textsubscript{2}), which supported the interpretation of the observation of inelastic tunneling strongly. Spatially resolved maps of the inelastic tunneling channels allowed the distinction and characterization of the two isotopes. It is believed that vibrational microscopy will have great potential for the determination of the identity and the arrangement of functional groups within a single molecule, and also for the characterization of small molecules in more complex chemical or biological environments.

Signatures of inelastic electron tunneling processes can also be observed by the detection of photons emanating...
Figure 14 Tunneling electrons can excite a molecular vibration of energy $h\nu/e$. The increase in conductance at this threshold is typically small ($< 1\%$). Therefore, inelastic electron tunneling spectroscopy (IETS) is usually performed by measuring the second derivative of the current–voltage curve: $d^2I/dU^2(U)$. 

from an STM-type tunnel junction.$^{(49)}$ The combination of STM with optical methods offers many attractive features with regard to spectroscopic contrast mechanisms which may add “true color” to the STM images.$^{(50)}$ 

2.7 Scanning Tunneling Spectroscopy with Laser Excitation

STM with simultaneous laser excitation can reveal chemical contrast on multicomponent semiconductor surfaces down to the atomic level.$^{(51,52)}$ The use of coordinated electronic and photon biasing has been demonstrated to provide atom-specific imaging, e.g. for CuInSe$_2$, a covalently bonded semiconductor with applications for thin-film photovoltaic technologies. It is assumed that the photon bias at a particular wavelength directly excites the atom, with the wavelength corresponding to the atomic transition probability. This method has been applied to study the local chemical order in the vicinity of defects, such as grain boundaries.

2.8 Subsurface Information by Scanning Tunneling Microscopy on Semiconductors

In contrast to metals, electric fields in semiconductor samples are not screened within a near-surface region but penetrate several nanometers into the sample. Therefore, subsurface information, e.g. about the distribution and electronic properties of dopants, can be obtained. As a rule of thumb, the depth up to which dopants are visible in STM images is given by the screening length in the semiconductor which itself is determined by the dopant concentration.

Figure 16 shows an atomically resolved STM image of a cleaved n-InAs(110) surface. Atomic rows of the As sublattice are visible because a negative sample bias was applied (see section 2.2). In addition, a 0.5 Å high elevation with a full width at half-maximum (fwhm) of 10 nm is observed. Such elevations are caused by charged dopants,$^{(53,54)}$ which can easily be verified since the number of the elevated features scales with the dopant
concentration. A simple model is able to reproduce the elevations qualitatively.\(^{55}\) It assumes that the screened Coulomb potential of the ionized dopants leads to a local band bending which shifts the LDOS \(n_s(E)\) of the sample according to Equation (27):

\[
n_s(E, x, y) \propto \sqrt{E - E_{\text{CBM}}(x, y)}
\]

where \(E_{\text{CBM}}\) is the energy of the local conduction band minimum. The resulting apparent height change \(\Delta z\) in constant-current images can be calculated to a first approximation by solving Equation (28):

\[
I \propto \int_0^{eU} n_s(E, x, y) \times \exp \left( -2 \frac{2m}{\hbar^2} \left( \phi + \frac{eU}{2} \right) z(x, y) \right) dE
\]

where \(\phi\) is the local tunneling barrier height, which has to be determined independently (see section 2.3).

By making use of the spectroscopic capabilities of the STM (see section 2.1) at low temperatures it is even possible to observe the scattering of electron waves at the attractive potential of ionized dopants,\(^{56}\) as shown in Figure 17.

3 SCANNING NEAR-FIELD OPTICAL SPECTROSCOPY

SNOM combined with optical spectroscopy probably offers the richest variety of experimental methods for chemical-selective imaging by scanning probe methods (SPM) in the nanometer-scale regime.\(^{43}\) It is well known that the spatial resolution achieved in classical optical microscopy is limited by diffraction to about \(\lambda/2\), where \(\lambda\) is the optical wavelength. This limit arises because the evanescent waves carrying the information about the high-spatial-frequency components of the diffracted
waves decay rapidly with distance \( s \) from the object. As a result information about subwavelength features of the object cannot be retrieved in the far-field regime of classical optics. On the other hand, by approaching a sharp optical probe within the near-field regime \( (s < \lambda) \), the diffraction limit of classical optics can easily be surpassed.

In the first SNOM experiments a tiny aperture, illuminated by a laser beam from the rear side, was scanned across a sample surface and the intensity of the light transmitted through the sample was recorded. The optical probes are usually formed by a sharpened glass or fiber tip coated with a thin metallic layer, leaving a submicrometer aperture at the apex. The capability of fabricating nanometer size apertures is essential to obtain high spatial resolution which, however, is gained at the expense of signal intensity. As an alternative to glass or fiber tips, sharpened micropipets coated with a thin metallic layer can serve as optical probes as well. The micropipet apertures can either be illuminated from the rear side by a laser beam, acting as a light source, or they can be used as collectors for radiation from a small area of the sample which itself is illuminated as a whole. To enhance the transmission of electromagnetic energy through the narrow micropipet tube, it has been proposed to fill the micropipet with a fluorescent dye.

SNOM can be performed in reflection, in addition to transmission, which is of great practical importance.
Figure 20 (a) Topographic STM image of a mixed film of silver and gold and (b) simultaneous SNOM image obtained with a tetrahedral tip (scan range: 125 × 125 nm). The contrast between silver and gold grains can be explained by the difference in the dielectric constants of silver and gold at optical frequencies. The transition from dark (Ag) to bright (Au) regions is limited to a width of less than 1 nm in this case.

Other important applications of SNOM include the detection, microscopy and spectroscopy of single molecules and the local spectroscopic studies of individual semiconductor quantum well, quantum wire and quantum dot structures.

4 FORCE MICROSCOPE-BASED TECHNIQUES

4.1 Theory and Methods

The SFM instrument is based on a miniaturized force sensor consisting of a cantilever-type spring with integrated sharp tip. The force interaction between the tip and the sample after approaching each other causes the cantilever to deflect by $\Delta z$ according to Hooke’s law:

$$F = c \Delta z$$

where $c$ is the spring constant. These deflections can be measured with high sensitivity by optical methods (laser interferometry or laser beam deflection), achieving a resolution of 0.1 Å or better (Figure 21). For a given spring constant of the order of $1 \text{N m}^{-1}$, the deflections can be measured with high accuracy by optical methods (laser interferometry or laser beam deflection), achieving a resolution of 0.1 Å or better (Figure 21). For a given spring constant of the order of $1 \text{N m}^{-1}$, the deflections can be measured with high accuracy.

Figure 21 Principle of the scanning force microscope. Bending and torsion of the cantilever are detected simultaneously by measuring the lateral and vertical deflection of a laser beam while the sample is scanned in the x–y plane. The laser beam deflection is determined using a four-quadrant photodiode: $(A + B) - (C + D)$ is a measure of the bending and $(A + C) - (B + D)$ a measure of the torsion of the cantilever, if $A$, $B$, $C$ and $D$ are proportional to the intensity of the incident light of the corresponding quadrant.

Including the exploitation of luminescence and polarization and also phase contrast (Figure 19), chemical contrast by SNOM has recently been demonstrated down to the nanometer scale. Figures 20(a) and (b) show an STM image (a) and a simultaneously obtained SNOM image of a mixed film of silver and gold (b). Grains as visible in the topographic STM image appear either dark or bright in the corresponding SNOM image which has been explained by the difference in the complex dielectric constants of silver and gold at optical frequencies. The transition from dark (Ag) to bright (Au) regions is limited to a width of less than 1 nm in this case.
measurable forces are as small as $10^{-11}$ N. A topographic map of a sample surface is obtained by keeping the interaction force constant while scanning the sample relative to the tip. SFM can be operated either in the contact regime, similar to the use of a stylus profilometer but with considerably lower forces, or in the noncontact regime. In the contact mode, short-range ion–ion repulsion forces are probed whereas in the noncontact mode SFM is exclusively sensitive to long-range forces, such as VDW or electrostatic forces. Two basically different modes of operation of SFM exist, i.e. quasistatic or dynamic operation mode.\(^{(7)}\) In the quasistatic mode, the interaction forces are directly detected via measurements of the cantilever deflection $\Delta z$ and the use of the relationship expressed by Equation (29). In the dynamic mode the cantilever is oscillated close to its resonance frequency and changes in the resonance frequency are measured resulting from tip–sample force interactions. Such changes can be explained to first order by a modification of the effective spring constant of the cantilever according to Equation (30):

$$c_{\text{eff}} = c - F'$$  \hspace{1cm} (30)

where $F' = aF/az$ is the gradient of the force acting between tip and sample. An attractive tip–sample force interaction with $F' > 0$ will soften the effective spring ($c_{\text{eff}} < c$), whereas a repulsive tip–surface force interaction with $F' < 0$ will strengthen the effective spring ($c_{\text{eff}} > c$). The change in the effective spring constant causes, in turn, a shift in the resonance frequency $w$ of the cantilever according to Equation (31):

$$w = c_{\text{eff}} m^{1/2} = \left( \frac{c - F'}{m} \right)^{1/2} = w_0 \left( 1 - \frac{F'}{c} \right)^{1/2}$$  \hspace{1cm} (31)

where $m$ is an effective mass and $w_0$ is the resonance frequency of the cantilever in the absence of a force gradient. An attractive force will therefore lead to a decrease of the resonance frequency ($w < w_0$) whereas a repulsive force will lead to an increase ($w > w_0$). However, Equation (31) assumes that the force gradient is constant over the whole distance range of the oscillating cantilever. This is usually not the case, leading to more complicated relations between frequency shift and tip–sample interaction.

In the case of frequency modulation (FM) detection of oscillation frequency changes, the minimum detectable force gradient $F_{\text{min}}$ is given by Equation (32):

$$F_{\text{min}} = \frac{1}{A} \left( \frac{4\varepsilon k_B T B}{w_0 Q} \right)^{1/2}$$  \hspace{1cm} (32)

where $A$ is the r.m.s. amplitude of the cantilever oscillation, $Q$ is the quality factor of the cantilever and $B$ is the detection bandwidth. To achieve the highest possible detection sensitivity for a given oscillation amplitude $A$ and detection bandwidth $B$, the mass of the cantilever should be as small as possible and the quality factor as high as possible (e.g. by operation under high-vacuum conditions). In addition, operation at low temperatures is preferable. Under these conditions, forces well below $10^{-12}$ N can be measured.

Various modes of SFM operation have been exploited in order to achieve the goal of chemical-specific imaging. In the following, three examples for the contact regime and two examples for the noncontact regime will be discussed.

### 4.2 Lateral Force Microscopy

Besides measuring the forces normal to the sample surface by detecting the induced bending mode deflections of the cantilever in this direction, it is also possible to study the lateral (frictional) forces with SFM by detecting the induced torsion mode deflections of the cantilever while scanning.\(^{(7)}\) According to Amontons’ law, as derived for macroscopic contacts, the frictional force $F_l$ should be proportional to the loading force $F_l$ in the normal direction (Equation 33):

$$F_l = \mu F_l$$  \hspace{1cm} (33)

where $\mu$ is the friction coefficient which is material dependent and therefore chemical specific.\(^{(59)}\) However, for a microscopic tip–sample contact, as realized in SFM, Equation (33) is no longer valid and the dependence of the frictional force on the applied loading force becomes nonlinear (Figure 22j). As a result, the contrast in lateral force microscopy (LFM) depends on the loading force in addition to the chemical species involved.\(^{(60)}\) This is illustrated in Figures 22(a–i), where the lateral or frictional force maps of a $C_{60}$ thin film on a GeS(001) substrate are presented for a series of loads $F_l$ applied to the area of contact between tip and sample. Dark colors in LFM images represent low friction force areas whereas bright colors represent high friction force areas.

The LFM maps in Figures 22(a–i), obtained with loads below 10 nN, exhibit lower frictional forces on the GeS substrate compared with the $C_{60}$ islands. At approximately 10 nN (Figure 22f) this contrast vanishes and finally flips as the load rises [Figures 22g–i]. At high loads, the $C_{60}$ islands therefore exhibit lower frictional forces compared with the GeS substrate. It is clear that the “chemical contrast” achieved in this model case critically depends on an external parameter, the applied loading force, and that an assignment of chemical species is not possible without understanding the details of the tip–sample contact mechanics. To study the origin of the
observed friction contrast reversal as a function of the applied load in more detail, the quantitative dependence of the frictional force on the applied loading force for the GeS substrate and the C₆₀ islands have to be measured as shown in Figure 22(j). The behavior of the frictional force on the C₆₀ islands (2/3-power law dependence) is markedly different compared with the behavior on the substrate (linear dependence). As a result, the two data sets exhibit a crossing point, which corresponds to the contrast reversal in the spatially resolved measurements. Consequently, the interpretation of friction force maps in terms of chemical contrast requires a careful analysis of

Figure 22 (a) Constant-force image of a 1.2 monolayer thin film of C₆₀ on a GeS(001) substrate (scan size: 2 × 2 µm) (b–i) Corresponding friction force maps for the same area at different loading forces of (b) 1.3, (c) 2.6, (d) 4.5, (e) 6.7, (f) 10, (g) 15, (h) 20 and (i) 30 mN. A friction contrast reversal is observed between images (f) and (g) which can be understood by a different friction-load dependence (j) for the C₆₀ thin film and the GeS(001) substrate. (j) Friction-load dependence for a C₆₀ thin film and a GeS(001) single-crystal substrate.
the local friction force spectroscopic data. The situation is analogous to STM or STS: the applied loading force as an important external parameter in LFM studies plays a similar role as the applied sample bias voltage in STM. Again, a combination of local spectroscopic measurements with spatially resolved imaging is required in order to obtain data with clear chemical contrast and clear assignment of the chemical species.

Lateral forces also play an important role for the interpretation of atomic-scale SFM images obtained in contact mode (Figure 23). Since typical loading forces exerted by the tip on the sample during measurement are of the order of 1–100 nN, up to several hundred tip atoms are in contact with the sample surface. Owing to a “stick-slip”-type motion of the tip the surface periodicity of a crystalline sample is still resolved. However, the unit cells often show an artificial shape (Figure 23). In addition, the atomic structure within each unit cell is not resolved. On highly reactive surfaces, e.g. on semiconductor surfaces with unsaturated dangling bonds, it is particularly difficult to obtain high resolution in contact mode. In this case, dynamic force microscopy (see section 4.6) has to be applied.

Figure 22 (Continued)

Figure 23 SFM image of a cleaved LiF(001) surface with unit-cell resolution obtained in the static contact mode. The contrast is governed by lateral forces acting on the tip in the contact region leading to a square-like appearance of the unit cell (scan size: $3 \times 3$ nm).
4.3 Adhesion Force Mapping

Adhesion forces can be determined by retracting the tip upon contact formation while monitoring the force necessary to break the contact. By repeating this procedure at different locations adhesion force maps can be obtained which can help to distinguish between different chemical species with different adhesion properties. This method can also be applied to molecular species for which specific molecular interaction mechanisms based on the existence of geometrically complementary surfaces of recognition sites provide a means to obtain molecular fingerprints. Examples of such SFM studies include molecular recognition between receptor and ligand, antibody and antigen and complementary strands of DNA.

4.4 Force Modulation Microscopy

By modulating the tip–sample force interaction in the contact regime, spatial variations in local surface elasticity can be probed. This method is based on modulating the sample height \( z \)-position) by a fixed amount \( \Delta z_s \). Motion of the sample causes the cantilever to deflect periodically by an amount \( \Delta z_c \). For a given applied loading force, a soft surface region deforms more than a hard one. Consequently, the measured cantilever deflection \( \Delta z_c \) is smaller over a soft surface region. By plotting the normalized quantity \( \Delta z_c / \Delta z_s \) as a function of surface location, a spatial map of surface elasticity can therefore be obtained. Applications include chemical-selective imaging of composite materials and biological specimens. Alternatively, SFM can be operated in the so-called tapping mode, being sensitive also to mechanical material properties.

4.5 Noncontact Force Microscopy

In the noncontact regime, the tip–sample interaction is governed by long-range VDW forces if tip and sample are neither electrostatically nor magnetically charged. The VDW forces acting between two macroscopic bodies can be calculated to a first approximation by assuming the VDW forces to be additive. For a sphere of radius \( R \) (tip) held at a distance \( s \) from a surface, the total force is given by Equation (34):

\[
F_{\text{VDW}}(s) = -\frac{H R}{6 s^2}
\]

where \( H \) is the Hamaker constant, which is material dependent and therefore chemical specific. Thus, by operating at a constant tip–sample distance, it is possible to distinguish between different chemical components due to the difference in the corresponding Hamaker constants.

4.6 Dynamic Force Microscopy with True Atomic Resolution

In dynamic SFM with true atomic resolution, a stiff cantilever with integrated atomically sharp tip is oscillated with a fixed amplitude at its resonance frequency in ultrahigh vacuum slightly above the sample surface (i.e. the amplitude chosen is close to the equilibrium tip–sample separation). The resonance frequency \( \omega_0 \) is affected by the force field acting between tip and sample, which includes both short- and long-range (VDW) force contributions. Image acquisition is accomplished by profiling the sample surface with a constant frequency shift \( \Delta \omega \). The strong distance dependence of the short-range forces allows true atomic resolution to be obtained by SFM comparable to the quality of STM data.

Figure 24 shows a dynamic SFM image of a cleaved n-InAs(110) surface with “true atomic resolution”, i.e. both atomic species, In and As, are resolved within each unit cell. In contrast to contact-mode SFM, the dynamic operation mode additionally allows the observation of single point defects such as As vacancies on the InAs(110) surface. Other important applications of dynamic SFM include the investigation of noble gas crystals and biological samples.
4.7 Magnetic Resonance Force Microscopy

Another SFM-derived technique which additionally offers great potential for three-dimensional (3D) chemical analysis is magnetic resonance force microscopy (MRFM). In MRFM a force signal is generated by modulating the sample magnetization with standard magnetic resonance techniques. Samples of only a few nanograms generate force signals of the order of $10^{-14}$ to $10^{-18}$ N, which can be detected by highly-sensitive microfabricated force sensors operated preferably under high-vacuum conditions and at low temperatures (Equation 32). Possible applications of MRFM include 3D imaging of biological specimens.

5 RELATED SCANNING PROBE TECHNIQUES

In addition to STM, SNOM and SFM, several other techniques exist which also have the potential for chemical-selective imaging. For instance, the scanning thermal profiler makes use of different thermal properties of different materials whereas the scanning near-field acoustic microscope exploits their different mechanical properties. Even in solution, chemical contrast can be achieved by scanning electrochemical microscopy based on the dependence of the Faradaic currents on the particular type of material.

SCM and spectroscopy has probably become the most important technique for the nanoscale analysis of semiconductor devices. SCM is based on the measurement of the capacitance between a doped Si tip (which might additionally be metal coated) and a semiconductor sample with a thin surface oxide layer (Figure 25). Spatial variations in the dopant concentration or type of doping cause changes in the measured capacitance. Since the electrostatic interaction involved has a long-range nature, information about subsurface properties can be obtained without the need for depth profiling. (Figures 26(a) and 26(b))

and (b) show an example of a DRAM device. The SFM image reveals the surface topography whereas the simultaneously obtained SCM image provides information about the locations of gate strips of transistor structures which cannot be deduced from the SFM image.

Although all STM-related scanning probe techniques offer additional complementary information about chemical inhomogeneities, the identification of the elemental species remains an unsolved problem.

### 6 PERSPECTIVE AND FUTURE DEVELOPMENTS

SPM have undoubtedly contributed significantly in recent years to correlate structural with local physical and chemical properties down to the atomic scale. The lack of elemental specificity is, however, a major challenge for future developments in which SPM might be combined with established methods for chemical analysis such as mass spectrometry or core-level spectroscopic techniques.

Microscopy is the art and science of visually observing small objects. Electrons are electrically charged subatomic particles typically responsible for the flow of electrical current. Scanning is a method of observation where the focus of attention is moved in a chosen pattern and desired information is gained by assembling observations in sequence. In a scanning electron microscope (SEM), a beam of electrons is scanned in a regular pattern over a small object, and the image of the object appears on a screen by displaying the image points in synchrony with the movements of the electron beam on the object.

A familiar example of image scanning is a television receiver, where a picture is created on a screen by rapidly scanning an electron beam across the phosphor face of the television tube. The beam striking the phosphor produces light, which is seen as a picture. The signal that modulates the electron beam in a television set is created in a television camera, which is scanned in the same way that the television screen is scanned. In a SEM, the signals come from special detectors in the microscope, not from an optical camera. Otherwise, the image display in a SEM is very similar to television. Although it is typical for SEM images to be scanned at a slower rate than are television signals, some SEMs display images at the same speed as television.

The most common signal for detection in a SEM is the secondary electron signal. Secondary electrons are low-speed electrons (having energies less than about 50 eV) that result from the interaction of the primary (i.e. beam) electrons with the sample. The secondary electrons are detected, usually by a scintillator/photomultiplier detector, and the resulting signal modulates the display screen.

Secondary electrons are popular because they provide a kind of shading that gives a three-dimensional appearance to an image, making it easy to visualize the structural relationships of parts of the sample (Figure 1).

Other signals provide information of a more analytical nature. The signal produced by backscattered electrons is directly (although not exactly proportionally) related to the atomic number of the material being struck by the primary beam. Diffracted electrons provide information about crystal spacings and orientations in the sample.
SURFACES

Figure 1 This photograph illustrates the essential features of scanning electron microscopy: large depth of field, high resolution, and an easily interpreted shading that gives the impression of a diffuse light source in the distance. The high resolution and large depth of field depend on the small wavelength of electrons and the small aperture angles that are used to define the electron beam. The appearance of diffuse illumination does not depend on the illuminating beam at all, but rather on the way secondary electrons are detected. (Reproduced by permission from A. Friedberger, R.S. Muller, ‘Improved Surface-micromachined Hinges for Fold-out Structures’, *J. Microelectromech. Systems*, 7(3) 315–319, copyright © 1998 IEEE.)

Induced-current signals are particularly interesting for studying the response of active electronic components.

The resolution of a SEM image depends on the quality of the optical system that forms the electron beam, including the nature of the electron source. Most SEMs can typically resolve objects as small as 10 nm. The resolution of specialized SEMs is better than 1 nm. In contrast, the resolution of light microscopes is limited by the wavelength of light to about 500 nm.

The magnification of a SEM is not directly related to the optical system, very unlike a light microscope. The magnifying power of a SEM is related to the ratio between the size of the scan on the object compared to the size of the scan on the image display. In this way a SEM functions like a mechanical pantograph that was used, typically in older days, for copying drawings. If the arms of the pantograph were of equal length, the drawing would be copied the same size. If the arms were adjusted to different lengths, the drawing could be magnified or reduced.

The primary advantage of a SEM is that it provides familiar-looking images of surfaces with higher resolution and greater depth-of-field than an optical microscope. Although the images are typically familiar looking, the contrast mechanism in a SEM is not the same as the contrast provided by light, and an observer expecting always to interpret a SEM image the same way as a light image could easily be fooled.

As the electron beam consists of electrically charged particles, the sample for SEM observation must either be inherently electrically conducting or must be made electrically conducting to yield good images. Otherwise, electrical charge builds up on the sample, the yield of secondary electrons is changed, and the scanning beam can become erratic. Low-voltage or low-vacuum SEMs can be used to reduce the charging problem.

1 INTRODUCTION

1.1 Overview of Scanning Electron Microscopy

A SEM is a versatile and efficient instrument for obtaining magnified images of small objects with a resolution better than that available with a light microscope. SEMs are available with a wide range of costs and capabilities. Scanning microscopes generally have an electron source, which creates a beam of electrons, an optical system, which focuses the electrons, a scanning system, which directs the beam over the sample, one or more detector systems, which create signals dependent on interactions of the beam electrons with the sample, and display systems, which allow the microscope operator to interpret visually the information produced by the microscope.

Light microscopes reached a fundamental limit to their ability to see small objects once the resolution of their optical systems approached the size of the wavelength of light. No matter how good the microscope lenses were, light itself could not reproduce an image of something smaller than its own wavelength. (Near-field scanning optical microscopes use light photons to produce resolution better than the light wavelength, but here the resolution is created by the scanning mode rather than by the light optics. This is a good analogy with the SEM, where magnification is provided by the scanning mode, not by the optical system.)

Among alternatives to light, electrons have a very small wavelength, much smaller than that of light, and they are relatively easy to produce and to focus. X-rays also have a small wavelength, but they are very difficult to focus. Electrons have an electric charge, so they can be focused and deflected with electric and magnetic fields. Protons and ions are charged, and therefore can be focused, but they are typically more difficult to produce than electrons. Electrons can be ejected from a solid by heating, such as commonly occurs with a tungsten filament or lanthanum hexaboride crystal, or they can be drawn out of a solid by field emission, a quantum-mechanical tunneling phenomenon. Field emission electron sources
are typically the smallest and the brightest, and they usually offer the highest resolution. Tungsten filaments produce the highest total electron current, although they allow a rather limited image resolution. Lanthanum hexaboride sources offer brightness and resolution that are less than field emission sources but more than tungsten filaments.

Once the electron beam is produced, it is generally focused by a series of cylindrically symmetric magnetic lenses to form a small spot on the sample. Because the image is created from the interaction of the beam with the sample, the highest image resolution comes from the smallest interaction spot. The objective lens is crucial in forming a small spot. Lens aberrations are directly related to the focal length of the lens, so the smallest focal length lens generally has the highest resolution. This fact typically leads to a trade-off, because a large working distance is very useful in providing flexibility in observing a variety of large samples, but a large working distance usually means a long focal length and hence a reduced resolution.

After the electron beam hits the sample, a large range of interactions can occur. Some electrons interact with atomic nuclei and are deflected back at large angles (called backscattered electrons). Some primary (beam) electrons create lower-energy secondary electrons that escape from the sample. Atomic and molecular electrons in the sample can de-excite, with the release of X-rays, light, and Auger electrons. Because the number of electrons leaving the sample is generally not equal to the number of electrons incident on the sample, there is a net electric current through the sample induced by the beam, and this current can be used as a signal to form an image.

In a scanning microscope, the beam typically generates a signal at one point on the sample and then moves to an adjacent point to obtain another reading of the same signal. Then the beam continues to move by small increments and continues to record the signal. A spot on a display screen is moved in synchrony with the spot on the sample. If the signal is low at one spot on the sample and high at another spot, typically the display screen will be dim at the first spot and bright at the second. If the spot on the display screen moves 1 mm every time the spot on the sample moves 1 µm, then the screen will show a magnified image of the sample (with a magnification of 1000× in this case). Unlike a light microscope, the lenses of the scanning microscope do not need to be changed to allow the magnification to be changed. It is only necessary to change the ratio between the distance moved on the sample and the distance moved on the screen. Because of the simplicity of the scanning mechanism, devices for driving the scans and recording images can be constructed very easily and inexpensively.\(^\text{(2)}\)

### 1.2 Capabilities

A SEM will typically produce an image of higher resolution and depth-of-field than a light microscope. Because of the higher resolution, a SEM can produce an image with a higher useful magnification than an optical microscope. A SEM generally produces a surface image, because of the nature of the detectors that are typically used. A SEM generally can handle a larger sample than a transmission electron microscope (TEM), because a TEM typically has a smaller space in the objective lens available to hold the sample (the smaller space correlates with a small focal length which implies higher resolution).

A SEM can make use of a wide range of electron-induced signals from the sample to offer a variety of different kinds of information about the sample.

### 1.3 Limitations

The sample in a SEM must be observed in vacuum or, for specialized instruments, in a significantly reduced-pressure chamber. The sample must be conductive or must be made conductive for good images (except in a low-voltage SEM, where there can be a closer balance between the numbers of incident and emitted electrons, or an environmental SEM where charge neutralization can occur). Although SEM images often look realistic, the imaging modes are not the same as in a light microscope and misinterpretations can occur when too strong an analogy is assumed between imaging with light and electrons. Fundamental resolution limits are caused by properties of the electron source and electron optics in the microscope. Except for very specialized instruments, the resolution of a TEM will be better than the resolution of a SEM, primarily because of the optical properties of the respective objective lenses.

### 2 HISTORY

Electron microscopes, including SEMs, were demonstrated in Germany in the early part of the 1930s. According to Wells,\(^\text{(3)}\) the idea of a device using a scanning beam was patented in Germany as early as 1927 by Stintzing. A SEM of a kind that would be familiar now was developed from cathode ray tubes by Knoll in 1935.\(^\text{(4)}\) A similar kind of mechanism for making enlarged images was demonstrated in the USA by Burnett in 1938 at the RCA labs using television tubes.\(^\text{(3)}\) Goldstein et al.\(^\text{(1)}\) credit von Ardenne\(^\text{(5)}\) with the earliest description of the construction of a SEM. By 1942, Zworykin et al. at RCA had developed a SEM with many of the features of current designs,\(^\text{(6)}\) where electron optical elements focused a beam on the sample.
and a secondary electron signal was picked up with a photomultiplier detector. This group reported other far-sighted developments, including work with field emission sources. But there was always difficulty in obtaining an adequate signal-to-noise ratio in the images. By 1953, McMullan in England had made significant progress in improving image quality by using an improved electron detector.\(^7\) Improvements continued to be made,\(^8\) and a commercial SEM was announced in 1965 by Cambridge Instruments.\(^1\) Numerous other commercial designs followed.

### 3 SAMPLE PREPARATION

#### 3.1 Cleaning and Coating

A SEM is usually used to provide a realistic-looking image of the surface of a solid, so in many cases it is not desirable to modify the sample. Many vacuum-compatible materials can simply be placed in the SEM for observation without further preparation. In an environmental scanning electron microscope (ESEM), samples can continue to include some volatile components and cleaning is not needed. Some samples need to be cut to fit in the SEM chamber. Samples that are contaminated with dirt or oil are usually cleaned prior to observation. Depending on the solubility properties of the sample, it is commonly possible to wash the sample with detergent and water or with organic solvents.

Nonconducting samples typically need to be made conductive to produce good images in a high-vacuum SEM. Samples are usually sputter coated with a heavy metal, such as gold or platinum, to make them conducting. The sputter-coating method usually provides a more uniform coating over irregular surfaces than does vacuum evaporation. When it is desirable not to coat the sample with a metal, it is possible to coat the sample with carbon by vacuum evaporation. It would not be good to use a heavy metal coating, for example, if the goal is to use the backscattered electron signal to detect metal clusters in a polymer matrix.

#### 3.2 Embedding and Sectioning

Sometimes a SEM image of the interior of a solid sample is required. In this case, the sample can be cut to reveal the area required. Small samples, or soft samples, may need to be embedded in a hard epoxy resin before cutting in order to provide enough support to hold the sample. Some epoxy resins have conductive fillers that improve the conductivity of the sample, and these can be helpful for samples that will be examined by SEM. However, it can be helpful to use a transparent (nonconductive) epoxy resin when the location of the cut has to be determined visually. Other mounting materials are also available. Pressed mounts are used for samples that can tolerate higher pressure. After embedding, hard samples will usually be cut and polished to yield a cross-section. Softer materials can be cut with a microtome.

#### 3.3 Lapping and Polishing

The microstructure of a sample can easily be obscured by a random surface texture, such as at a cut made by a saw, so it can be helpful to make a smooth surface. In these cases, it is useful to lap and polish the sample surface that is intended for observation. Plastic lapping films containing diamond abrasives are very good for high-quality lapping. Sample surfaces can be lapped with films down to 0.5-µm abrasive particle size, and further polished with materials such as colloidal silica for an extremely fine finish. Methods such as this are particularly useful for visualizing the interior of semiconductor integrated circuits.

#### 3.4 Freezing and Cleaving

Some soft materials are not easily cut, or they suffer plastic deformation that yields a cut surface that is not useful for observation. In some cases, a more useful surface is obtained if the sample is frozen (for example, in liquid nitrogen), and is cleaved by a blow from a hard knife or by shear from clamps on opposite sides of the sample.\(^9\),\(^10\) Obviously care must be exercised to ensure safety. Shields and thermal insulators need to be used in observing and handling cold materials. It is important to avoid splattering cryogenic liquids.

#### 3.5 Modification of Ambient Conditions

ESEMs have been developed that require less stringent vacuum requirements in the sample region than typical SEMs. By controlling the atmosphere surrounding the sample in these instruments and the temperature of the sample stage, it is often possible to allow volatile components to remain in the sample and even to view hydrated samples directly. By controlling the environment around the sample, it is possible to reduce the necessity for coating samples with metal.

### 4 MICROSCOPY OF SURFACES

#### 4.1 Resolution Limits with Tungsten Sources

The whole purpose of microscopes is to make a magnified image, so it might seem strange that the optical system of a SEM has nothing to do with magnification. As noted
above, the scanning system of a SEM is what creates the magnified image. The optical system of a SEM is actually a demagnifying system. The lenses of a SEM are used to focus the electron beam to a small point on the sample and, the smaller the point, the better the resolution. As the size of a tungsten filament is a substantial fraction of a millimeter, and the desired resolution of the microscope is a small fraction of a micrometer, the demagnification of a SEM optical system has to be at least 1000×. For 10 nm resolution with a tungsten source, the demagnification is typically around 1/30000.

The ultimate limitation on the resolution of a SEM is the electron source, because no amount of demagnification of the source can make the image point brighter than the source. In classical mechanics that fact would be expressed as a consequence of Liouville’s theorem on the conservation of phase space, but in electron optics reference is made to Langmuir’s equation. The brightness of the electron source is the current density per solid angle, which can be given by Equation (1)

\[ \beta = \frac{i}{s\Omega} \]  

where \( \beta \) is the brightness, \( i \) is the beam current, \( s = \pi r^2 \) is the area of the beam, \( r \) is the radius of the beam, and \( \Omega = \pi a^2 \) is the solid angle subtended by the beam, where \( a \) is the divergence angle (semivapex angle) of the beam (measured, for example, at the gun cross-over, beyond which the electron energy is constant). Demagnification cannot increase the brightness. Also, because the aberrations of electron lenses require the acceptance angle to be limited in order to maintain resolution (see below), beam intensity is actually lost on the aperture stops used to limit the lens acceptance angles. With additional demagnification the beam becomes dimmer and dimmer until the signal is inadequate to make a picture in a reasonable amount of time. The statistical standards for deciding what are adequate signal levels were worked out first for television pictures, but the same statistics apply as well to scanning microscopes.

A tungsten filament is the largest of the electron sources typically used in electron microscopy. Although such a filament can produce large amounts of current, the current is spread over a large source size, so the maximum brightness is limited. A tungsten hot filament may have a brightness \( \beta \) of \( 10^4 \text{ A cm}^{-2} \text{ sr}^{-1} \) at 25 kV.\(^{[3]}\) A certain amount of brightness is needed to provide an image that is good enough to allow the microscope to be focused and an image to be recorded. In practical terms, resolutions better than 10 nm are difficult to achieve with a tungsten hot filament without facing serious intensity limits.

### 4.2 Resolution Limits with Hexaboride Sources

Lanthanum hexaboride filaments are an improvement over tungsten, first because of higher brightness. The source size is smaller and the resulting electron beam is brighter. That produces better image resolution.

Another advantage of a hexaboride source is that it operates at a lower temperature, causing less evaporation of the filament and hence increasing lifetime. For instruments that are heavily used, this is an operational advantage. This advantage was noted by Broers, who was primarily responsible for the development of practical lanthanum hexaboride guns.\(^{[13]}\) A disadvantage is that the hexaboride crystal can be easily poisoned by contaminants, requiring a better vacuum system than is typical with tungsten filaments.

The brightness \( \beta \) of a lanthanum hexaboride gun can be \( 10^8 \text{ A cm}^{-2} \text{ sr}^{-1} \) at 25 kV.\(^{[3]}\) Instrumental resolution of 1 nm is possible with lanthanum hexaboride sources.

### 4.3 Resolution Limits with Field Emission Sources

Field emission tips are the smallest of the electron sources typically used in electron microscopy, and the brightest. The first practical SEM with a field emission source was developed by Crewe et al.\(^{[14]}\) Because of the curvature of the electric field lines around the tip, the effective source size is a few tens of nanometers, so a demagnification of 1000× can produce a resolution approaching 0.1 nm.\(^{[15]}\) With such a small demagnification, there is adequate brightness for recording high-resolution pictures.\(^{[16]}\) The brightness \( \beta \) of a field emission gun can be \( 10^8 \text{ A cm}^{-2} \text{ sr}^{-1} \) at 25 kV.\(^{[3]}\)

Another advantage of field-emission tips is that they can be operated with little heating, or even at room temperature. Field emission is a quantum-mechanical effect. The electrical potential at the surface of a metal usually keeps electrons inside, and energy usually has been added as heat to allow the electrons to escape (which happens with tungsten filaments, for example). With field emission, an extremely high electric field is applied to the tip to make the electrostatic barrier very thin. Although the barrier is still there, the quantum-mechanical uncertainty principle makes it possible for electrons to appear on the other side of the barrier, where they can form the electron beam that is used in the microscope.

A disadvantage of the field emission source is that vacuum conditions must be excellent. An ordinary vacuum would allow the formation of heavy ions that could bombard the tip and destroy it. Adsorbed atoms can adversely affect the local work function of the metal, leading to increased instability of the beam.
4.4 Resolution Limits with Traditional Scanning Electron Microscope Objective Lenses

Although the ultimate resolution of a SEM is limited by the electron source, the useful resolution of a SEM over practical magnification ranges is set by the probe-forming lens (sometimes called the objective lens, by analogy with other kinds of microscopes). Lens aberrations and diffraction are lens defects that limit resolution. Electron-optical lenses used for focusing electrons are much worse than glass lenses for light. Whereas chromatic and spherical aberration can be corrected in the construction of glass lenses, it has been proved that spherical aberration can never be removed from the cylindrically symmetric magnetic fields typically used as electron lenses (although it is possible to build noncylindrical correctors – see below). The spherical aberration coefficient $C_s$, which indicates the unsharpness of a focal point, is related to the focal length of an electron lens. The longer the focal length, the larger the aberration. Spherical aberration is also related to the aperture size of the lens. The minimum focal spot size $d$ is given by Equation (2)

$$d = 0.5 C_s \alpha^3$$

where $\alpha$ is the beam angle defined by the aperture. The wider the aperture, the larger the unsharpness. To limit the aberration, the aperture must be kept small (thus limiting the beam intensity, which is why it is not practical to use extreme demagnification to make a high-resolution microscope).

The focal length of the lens has to be adjusted to accommodate the working distance between the lens pole piece and the sample. To look at large irregular samples, it is often necessary to keep the sample away from the lens, so the beam has to focus far from the pole piece. This long distance creates larger aberrations.

To allow the most flexibility in dealing with large and irregular samples, the most common lens for SEM instruments was designed to take an electron beam coming from one side of the lens and focus it to a point on the other side of the lens, outside of the major part of the magnetic field. Keeping the sample outside of the magnetic field also makes possible the most efficient collection of secondary electrons, which are commonly used for imaging samples in a SEM. Such a design has the longest focal length, and the lowest resolution.

4.5 Resolution Limits with Immersion and Semi-immersion Objective Lenses

For high resolution, the best place for the sample is directly inside the lens, where the magnetic field of the lens is highest. Here the curvature of the electron beam is high, and the focal length is very short. This produces the smallest aberration coefficients, but only small samples can fit inside such lenses.

An interesting disadvantage of this high-resolution immersion design in a SEM is that secondary electrons, which are typically detected in a SEM, cannot escape from the magnetic field of the lens. In such a microscope, a secondary electron detector at the side of the chamber, which is the usual location, would detect few electrons. This was solved by placing the secondary detector above the lens, where the electrons could spiral up the lens field to reach it. There are also other detector designs to solve this problem.

A more recent semi-immersion lens design, the snorkel lens, is a compromise between the fully exterior probe and the immersion lens. The exit pole piece of the lens is constructed to squeeze the magnetic field out toward the sample, so the magnetic field will be near the sample even though the sample is outside of the lens. This allows a short focal length with a sample that is exterior to the lens, allowing larger samples than the full-immersion lens and much higher resolution than the probe lens.$^{(17)}$

Each of these two modes (immersion and probe) have their advantages, so one manufacturer has introduced an electron optical column with extra lenses that allows switching between semi-immersion mode and external-probe mode.$^{(18)}$

To go beyond the fundamental resolution of the cylindrically symmetric electron objective lens, it is necessary to correct the spherical aberration inherent in such lenses. As noted above, for a SEM the optics needed to focus on the sample are totally independent of the mechanism of producing magnification. The improvement of the sharpness of the lens can be done before the beam is scanned to produce magnification. For that reason, an aberration corrector for a SEM only needs to correct the on-axis aberrations, whereas for a TEM it is necessary to correct off-axis aberrations. For a SEM, a corrector has been constructed that has improved the resolution of an instrument operating at 1 kV from 5 nm to below 2.5 nm.$^{(19)}$

Combining a field-emission source with a full-immersion lens can produce impressive resolution at higher voltages. One commercial producer offers a field emission scanning electron microscope (FESEM) with 0.24 nm resolution at 200 kV.$^{(20)}$ designed primarily to detect electrons passing through the samples and intended for the semiconductor industry.$^{(21)}$

4.6 Contrast and Resolution Limits with Secondary Electrons

Because the scanning beam only strikes one point of the sample at a time, it is not necessary to focus the electrons as they exit the sample to make an image on a screen. Any
group of exiting electrons can be detected to produce an image. The scanning mode produces the image, point-by-point. The detector only needs to tell the microscope how bright each point should be. Not only does this give great freedom in selecting what signal is used to produce the image, it allows the possibility of detecting many signals simultaneously. Secondary electrons and backscattered electrons are examples of such groups of electrons. Electron-induced signals of other types can also be detected, such as cathodoluminescence photons or elementally specific X-rays (these signals are discussed in section 4.6 and Electron Microscopy and Scanning Microanalysis).

Secondary electrons are electrons of less than 50 eV energy that are induced by the primary electrons (beam electrons). Because of their low energy, secondary electrons have a small escape depth (of around 3 nm\(^2\)) in carbon), so they are capable of yielding images with resolution of this same scale. (However, secondary electrons created at the exit surface of backscattered electrons can confuse this resolution, as distinguished from the secondary electrons resulting from the incident primary beam.)

The low energy of the secondary electrons also makes it easy for the electrical potential on the secondary electron detector to pull the secondary electrons around small obstructions to reach the detector. This effect is one of the main reasons why the secondary electron signal produces such a pleasing three-dimensional appearance in the micrographs. It is very easy to look at a SEM secondary electron image and imagine viewing a landscape from a high vantage point.

The limited escape depth of the secondary electrons is also involved in another contrast effect that enhances the appearance of edges. When a primary electron is incident perpendicular to a surface, it generates secondary electrons from only a short distance inside the solid. When a primary electron enters a surface at a glancing angle, it can travel inside the solid at a position still near the surface, so secondary electrons can escape for a considerable length of the primary electron’s path. As the glancing electron develops more secondary electrons than a perpendicular primary electron, the signal corresponding to the glancing electron is higher, and the image point is brighter. This kind of situation happens particularly at edges, where primary electrons can generate many more secondary electrons, so edges are frequently bright in secondary electron images.

In addition to geometrical effects, contrast in secondary electron images depends on the properties of the materials being struck by electrons. The secondary electron yield is different for different materials, causing significant contrast between substances. One of the reasons that gold is often preferred as a coating material for SEM samples, rather than carbon for example, is that gold has a particularly high secondary electron yield.

4.7 Contrast and Resolution Limits with Backscattered Electrons

Backscattered electrons have a relatively high energy, so they can scatter from the atoms of a solid and travel a considerable distance in the solid. For that reason, the resolution of images from backscattered electrons can be limited. This degree of scattering is dependent on the accelerating voltage of the primary beam, so resolution can be improved at lower voltages. If the backscattered electrons are energy filtered, the resolution can be improved by limiting the collection of electrons to those that have scattered only once or a few times (by elastic scattering). As backscattering is heavily dependent on elastic electron scattering from the electrostatic field of the nucleus of atoms, the backscattered signal is predominantly atomic-number dependent. The backscattered signal can be used to make an image show contrast that is specific to the materials being illuminated by the electron beam.

As the backscattered electrons are of higher energy, they mostly travel in straight lines and they do not yield softly lighted images, such as those generated by secondary electrons. Typically a backscattered-electron image is more dependent on material contrast than on geometrical contrast. Some manufacturers provide a segmented backscattered electron detector that allows backscattered electrons from one direction to be contrasted against backscattered electrons traveling in another direction. This system introduces some geometrical contrast into an image produced by backscattered electrons.

Electrons can also be reflected back to a detector by diffraction from a crystal lattice (backscattered electron diffraction), or the escape depth can be modified by the direction of travel through a crystal lattice (electron channeling). These signals can be useful for studying crystalline materials or localizing grain boundaries in metals.

5 APPLICATIONS TO MINERALS

Being quick and efficient instruments with which to produce images with better resolution than light will allow, SEMs have been in routine use for decades. There have been so many applications of SEMs that it would be impossible to provide an adequate review in a limited space. In this and following sections, a variety of
recent applications are described that may provide some interesting and useful examples of possible uses of SEMs.

Minerals have a variety of compositions and a variety of crystal structures. One striking advantage of SEMs is that the beam can provide an image of sample morphology at the same time as providing a measure of elemental composition through energy-dispersive X-ray spectrometry. This important capability of elemental analysis is described in section 5.

A controversy over the age of a wall painting in the American Southwest provided a good example of the value of SEM in analyzing the microstructure of mineral products. The pictograph, called the All American Man because of its red, white, and blue decoration, may have been painted on the wall of a cave at a time before the USA was created and before the well-known red, white, and blue flag was adopted by the USA. However, it was also possible that the painting was made, or was redecorated, after the founding of the USA, because the shield motif of the painting was so reminiscent of the stars and stripes common in the USA, and the colors were so similar to the red, white, and blue of the flag. To determine if the design predated the USA, it was necessary to identify and date the pigmented layers of the pictograph.

Analyzing flakes that fell off the wall (so the wall painting itself would not be further damaged) a SEM was used to characterize the layers that made up the paint decoration. Once the layers were confirmed morphologically, carbon dating techniques were used to demonstrate that the pigments of the pictograph dated from the 1400s, prior to the founding of the USA. In the presence of phosphate, small irregular shapes, such as polygons, plates and fibers, were observed to form between the crystallites of calcium aluminate hydrate, and appeared to be involved in enhancing the strength of the cement.

The cast material can then be removed from the feature and be observed by SEM. Such casts have been used in a study of ancient drills, where a SEM was used to produce information about the drill types used in the Indus Valley in ancient times. The surface structure of minerals may yield clues to reactivity, and the enhanced resolution of a FESEM is useful in detailing the surface structure. A recent study considered the use of rice-husk ash as a silica source for the formation of zeolites. X-ray diffraction was used to identify amorphous silica, but not all of the silica identified this way proved to be equally reactive. Nuclear magnetic resonance was used to investigate the local structure of the silica, finding the atomic bonding arrangement that was associated with the most reactive samples. The surface structure of the most reactive silica was examined by a FESEM, and these samples showed clearly defined parallel layers of sharp flakes interleaved with smoother surface features. The smoother features were also present in the less reactive samples but the sharp flakes were not prominent, suggesting that the sharp flakes were indicative of the structure of the more reactive silica.

Another specialized SEM, the ESEM, allows the sample to be held in a special environment of temperature and pressure instead of in the high vacuum that is typical for SEMs. The structural changes involved in the curing of cement can only be observed in real time when hydration is allowed, which is possible with an ESEM. By using an ESEM, the evolution of microstructure was observed in high-strength high-alumina cement. In the presence of phosphates, small irregular shapes, such as polygons, plates and fibers, were observed to form between the crystallites of calcium aluminate hydrate, and appeared to be involved in enhancing the strength of the cement.

6 APPLICATIONS TO METALS

As the backscattered electron signal is related to the atomic number of the material illuminated by the electron beam, it is a useful signal for distinguishing areas of metals in other matrices, or in discriminating different metals. In a study of cosmetics from ancient Palestine, a protrusion was observed from a container that was being studied. A SEM was used to study cross-sections of the container, identifying the protrusion as a metal rod and discovering a second corroded rod nearby. Again, as in other studies, energy-dispersive X-ray spectrometry was used to identify the metals. Other techniques, such as Fourier transform infrared (FTIR) and X-ray diffraction, figured prominently in the study. However, in contrast to many other techniques, the backscattered electron
image provides an exceptionally rapid method for finding small areas of metal in lighter matrices. Such areas might not even be suspected without the initial screening by a SEM with the backscattered electron detector. After an anomalous area is discovered by a SEM, the composition of the area can be further studied by other more detailed, but slower, techniques.

The SEM provides morphological information with higher resolution than optical microscopes. In studying forensic evidence for wildlife enforcement activities, it is often useful to identify markings on bullets, shells or shotgun pellets that are obtained as evidence in the investigation of poaching or killing of protected animals, or other illegal hunting. By matching such marks with ammunition fired by suspected weapons, a case can be supported against individuals charged with illegal activities. In a study of the use of SEMs for such investigations, SEMs provided clearer matches of firing pin imprints than optical microscopy. In this same study, a SEM was also used to assist in the correlation of surface features on shotgun pellets.

Some surface features are so small that a FESEM is required to obtain the necessary resolution to see the objects. Nanocrystals of InAs were observed in a FESEM at 100,000× magnification in order to determine the size, orientation and distribution of the nanocrystals on a modified silicon surface. Such an observation is relatively quick to accomplish with a high-resolution SEM, whereas the same observation with a TEM would require the lengthy preparation of a plan-view sample. However, cross-section TEM was used in this study to illustrate the uniformity of the crystal lattice of the nanocrystals.

7 APPLICATIONS TO FIBERS

Fibers used for a variety of purposes have varying size, structure and orientation with respect to neighboring fibers. The surface structure of natural fibers often give clues to their plant source. The SEM is very useful in examining such surface structure, and the source of fibers in a given sample of fabric can often be deduced. It is a particular challenge to make such an identification of the fibers in an object as old as an ancient Egyptian mummy. By checking fiber surface substructure in the wrappings of an Egyptian mummy with a SEM, flax and ramie have been identified as constituents of the fabric. The study correlated the choice of fibers with the properties helpful for preserving the mummy.

The structural properties of products that contain fibers depend on the choice of fibers and also on the arrangement of the fibers. The strength of materials containing woven fibers is often nonisotropic, and the type of weave often determines some of the directional variables of the strength of the material. A SEM can be used to examine such questions. In the case of dental prostheses, the arrangement of the internal strengthening fibers have been studied by a SEM. By removing the solid matrix material surrounding the fibers, the strengthening fibers used in materials for the prostheses were observed by a SEM. The size of the fibers was measured and the weaves used in producing layers of fibers were identified.

Studies involving hydration are often essential in studying fiber products. Studies of the effect of water on paper, for example, can include the application of ink to printing paper or a water drop on absorbent paper. It would be impossible to study liquid water drops in a typical high-vacuum SEM. Such studies are perfect examples of opportunities for the use of an ESEM, where samples can be kept in a hydrated environment. The fibers of the paper do not need to be coated or otherwise treated to avoid charging when an ESEM is used. A variety of paper components and sizing agents were investigated by an ESEM in a recent study, yielding information about the spreading and absorption of water drops.

8 APPLICATIONS TO POLYMERS

The surfaces of special-purpose polymer layers can often be observed easily by a SEM. Testing a polymer surface for binding of platelets was needed when a NO-releasing membrane was proposed as a way to limit the fouling of sensors exposed to blood flow. Platelets are blood cells involved with blood clotting, and they attach easily to a wide range of polymers exposed to blood flow. Sensors designed to function while exposed to the blood circulation can often have a limited lifetime because of platelet binding. In a study comparing a NO-releasing membrane with other polymers, SEM images showed cells and biological materials bound to both membranes, but with far fewer cells attached to the active membranes.

Interior surfaces of solids can be observed in a SEM by preparing fractured samples. The strength of polymer mixtures is often correlated with the nature of the mixing of the components, and the mixing can be revealed by SEM observations of the domains formed in solids by the different components. Polymer mixtures can show different sizes and distributions of components, depending on the compatibilizers that are included in the mixtures. Boundaries of different components have different binding strengths, and a fracture through a mixed solid can give clues to the
strength of binding. If a fracture follows the interface between components, the binding of those components is less than the bulk; if the fracture goes through the bulk of a component, the binding to the nearby components is stronger than that within the bulk. Scanning electron microscopy of fractured samples can determine whether fractures follow interfaces between components or pass through components. A study of polystyrene–polypropylene mixtures showed that there was weak binding between components under some compatibilizer conditions, better adhesion in other conditions. By using an ESEM to allow higher vapor pressures than are typical of SEMs, the kinetics of the formation of layers from polymer mixtures can be studied.

Microelectromechanical systems (MEMS) devices are generally tiny machines that are constructed using methods that were derived from fabrication techniques developed originally for the microelectronics industry. Microelectromechanical structures often have surface features at the micrometer level (high resolution), whereas the devices can extend over millimeters (large depth-of-field). Light microscopes have too little depth of field at the necessary resolution to produce good images of many of these structures. The SEM is particularly valuable for observing MEMS devices because of extensive depth of field and good resolution. For pop-up structures, where components are fabricated on a plane and then are raised to a perpendicular or oblique angle, the need for a good depth of field is particularly important.

In the construction of micromechanical structures, it is typical to print patterns onto polymer resists by exposing the resist to light prior to development and then etching. Printing the patterns on the resist by electron-beam writing promises to yield higher resolution and smaller features. The ESEM is a valuable device for prototyping electron-beam lithography methods without needing to metal-coat or otherwise prepare the resist.

9 APPLICATIONS IN BIOLOGY

SEM’s have been widely used in biology and the number of applications is vast. Observations have been made of organisms (from insects to bacteria), cells (including blood cells and tissue cells), and even large molecular arrays (like nuclear pore complexes and muscle filaments). For the smallest objects, a FESEM is required. When hydrated samples need to be examined, an ESEM is appropriate. For many samples, a typical SEM is very productive. An excellent way to survey biological applications of SEM’s is by using one of several atlases dedicated to this topic.

For biological objects, hydration is often extremely important. Although hydration can be maintained in an ESEM, sometimes it is necessary to have more resolution than is available with an ESEM, or it might be necessary to prevent movement of the sample. In such a case, hydration can be maintained in high vacuum with frozen samples. Insects feeding on plant fluids can be observed when the sample is preserved in the SEM by freezing.

The search for specific molecules is often important in biology, and high-atomic-number elements can be bound to compounds that can be used for labeling specifically targeted molecules in a biological sample. The backscattered signal in a SEM is particularly useful for detecting and localizing heavy-atom label compounds in biological materials.

Determining the molecular weight is crucial in understanding the structure and function of components of molecular complexes, and a special kind of FESEM with a full-immersion lens is capable of making such measurements. The molecular weight of individual components can often be measured without removing them from their complexes, an advantage over biochemical techniques where purification is usually necessary. The mass of a molecule is determined by counting the number of electrons scattered from the molecule using a transmitted-electron detector; for that reason, this kind of instrument is often called a scanning transmission electron microscope (STEM). The repeating unit of some Neurospora helical filaments was found to weigh 90 kDa by the transmitted-electron method, suggesting a different ratio of molecular components than was indicated by quantitative gel electrophoresis.

Another study, which compared structural observation with molecular weight measurement, determined that the globular particle of a helical filament core in Leishmania consisted of a polypeptide dimer. It is very useful when the molecular weight can be determined in the microscope simultaneously with the observation of structure, as was also done in the determination of phage secretin multimer composition. Measurement of mass per unit area was found to be useful in modeling the molecular structure of the cell envelope of terminally differentiated keratinocytes (skin cells). A special STEM uses low temperature to preserve samples better while measuring molecular weight.

10 INSTRUMENT PERFORMANCE

10.1 Calibration

The standard calibration for SEM magnification in the USA is done using the NIST Standard Reference Material SRM 484G, which contains metal lines with certified
spacings. As an alternative, it is common to perform magnification calibration with secondary standards from a variety of commercial manufacturers and private laboratories. Secondary standards offer some advantages over the NIST reference, such as lower cost, higher contrast, or a greater variety of test patterns. To calibrate the magnification, typically the reference standard is photographed with the SEM in the conventional way, and the magnification is determined by dividing the measured size of the feature on the photograph by the certified size of the feature on the reference standard. It is valuable to calibrate the horizontal and vertical dimensions of the SEM image separately, because different chains of amplifiers are used to generate the scans in these perpendicular dimensions. In many cases SEMs have automatic readouts and scale bars that print the magnification on the photograph. In these cases it is useful to adjust the scan amplifiers until the printed magnification is equal to the calibrated magnification.

10.2 Resolution Tests
Because of the high contrast of gold in the secondary-electron image, it is common to observe the resolution of a SEM by photographing a surface covered with islands of evaporated gold of various sizes. Resolution is estimated by measuring the separation of the smallest features that can be determined to be distinct. A variety of both natural and fabricated test structures are also available for resolution testing.

11 COMPARISON WITH OTHER TYPES OF MICROSCOPY

11.1 Optical and Confocal Microscopes
Optical microscopy can quickly yield magnified images of samples, and the varying colors of different materials helps in making quick identifications. Also, light microscopes can be used to observe samples in liquid solutions, in air, or under a variety of other conditions that still allow an optical path to reach the samples. However, the resolutions of light microscopes are fundamentally limited by the wavelength of light itself.

An exception to this general rule is the near-field scanning optical microscope, where the resolution is set by a tiny aperture rather than by the wavelength of light. Here, like in a SEM, the image is created by scanning the aperture across the sample, which is why the resolution of the near-field scanning optical microscope is disconnected from the magnification. In a conventional light microscope, the optical system of lenses that create the magnification is also responsible for creating, and limiting, the resolution.

Because electrons have a substantially smaller wavelength than light, SEMs are fundamentally capable of higher resolution than light microscopes. Also, because of the small wavelengths of electrons, SEMs operate with a much smaller objective aperture angle than light microscopes, giving a large depth of focus that provides a satisfying depth of view into three-dimensionally extensive samples. This effect will be familiar to photographers who use manual cameras with control of the lens aperture. When photographing someone standing in front of the Grand Canyon, at f/16 (a small aperture) both the person and the canyon will be in focus, whereas at f/2 (a large aperture) the person will be in focus and the canyon will be blurry.

An exception to the limited depth of field of optical microscopes is another kind of scanning light microscope, the confocal microscope. In this instrument a point of light is scanned through the volume of a transparent sample while the illuminated point is imaged by the objective. The scanning mode creates depth information that can be displayed in three dimensions. Although this mode of image recording increases the distance into the sample that can be imaged with good sharpness, it does not significantly improve the fundamental resolution. Because the objective still images the illuminated point, the resolution of the confocal microscope is still limited by the wavelength of light.

11.2 Transmission Electron Microscope
TEMs typically have higher resolution than SEMs primarily because transmission microscopes use high-field immersion objective lenses with very small aberration coefficients. However, because electrons need to be transmitted through samples in a TEM, generally samples need to be very thin and substantial three-dimensional information is not available. Thinning the samples is a time-consuming process, so preparation of samples for a SEM is typically much quicker than for a TEM.

11.3 Atomic Force and Scanning Tunneling Microscopy
Atomic force microscopy and scanning tunneling microscopy are examples of the general class of scanning probe microscopy. These methods are like scanning electron microscopy, except that instead of an electron beam traveling over the sample, a physical mechanical probe is driven over the sample. The interaction of the probe with the sample makes the signal that makes the image. The signal is reproduced on a screen in synchrony with the probe’s position on the sample, in a way that is very similar to the process in a SEM. Because of the physical size of the probe, the depth of field of probe microscopes is typically much less than that of SEMs. However, because
small points on the probe are generally responsible for a majority of the signal, the scanning probe microscope can often have atomic-level resolution on flat samples.

ACKNOWLEDGMENTS

I thank Dr Gary E. McGuire of MCNC for encouraging this work, Ray Gundersdorff and Nancy Chrestensen of JEOL for providing information about JEOL instruments, Evan Slow of FEI for providing information about Philips instruments, and Elisa Carr of Hitachi Scientific for providing information about Hitachi instruments.

Scanning Probe Microscopy, Industrial Applications of

Axel Born
University of Hamburg, Hamburg, Germany

1 Introduction

The twenty-first century may be called the century of nanoscience. Chemistry, biology and physics, and especially semiconductor devices, will come together on the nanometer length scale. Physical, chemical and biological processes must be studied in real space and under environmental conditions. These requirements will push forward a new type of analytical tool, namely SPM. This technique is based on scanning tunneling microscopy (STM), which was developed in 1982 at the IBM Zurich Research Laboratory (Switzerland). Within 10 years it could be found in almost every laboratory around the world, and now, nearly 20 years later, SPM is being used not only in laboratories, but also in production. The purpose of this article to give an insight into the potential of SPM techniques in industrial applications today. Owing to the wide variety of possible applications, this article can present only a small selection of uses.

Since the early days of STM, many different types of SPM (Table 1) have been developed, all of which are based on the same principle: a small probe is brought in close proximity to the surface of a sample in order to measure near-field interaction (Figure 1). In most cases, feedback keeps the interaction strength constant during the passing of the probe across the sample. Scanning is achieved by means of piezoelectric actuators which define the set-up of the probe and sample with an accuracy of the order of a few picometers (10^{-12} m). We are then able to scan a probe across a sample at a distance smaller than the characteristic wavelength of the specific interaction (for STM and the wavelength electrons, this is a fraction of a nanometer, depending on the energy). The so-called near-field interaction regime permits a spatial resolution which is beyond the Abbe limitation.

STM gives us a panorama of conductive surfaces with atomic resolution. SPM has been used in biology, chemistry and physics. In biology, it is valued for its ability to measure in an ambient environment or an ionic solution. It is therefore possible to observe viruses, bacteria or cells in action (e.g. the pulsing of a heart cell) or the interaction between DNA and specific proteins. This cannot be done by using scanning electron microscopy (SEM) or transmission electron microscopy (TEM), because of the need for ultrahigh vacuum (UHV) conditions and/or metal coating. However, the achievable resolution of standard optical microscopy is limited to

The increasing number of companies that are using SPMs in the laboratory and manufacturing every day provides evidence of the rising popularity of SPM.

1 INTRODUCTION

The twenty-first century may be called the century of nanoscience. Chemistry, biology and physics, and especially semiconductor devices, will come together on the nanometer length scale. Physical, chemical and biological processes must be studied in real space and under environmental conditions. These requirements will push forward a new type of analytical tool, namely SPM. This technique is based on scanning tunneling microscopy (STM), which was developed in 1982 at the IBM Zurich Research Laboratory (Switzerland). Within 10 years it could be found in almost every laboratory around the world, and now, nearly 20 years later, SPM is being used not only in laboratories, but also in production. The purpose of this article to give an insight into the potential of SPM techniques in industrial applications today. Owing to the wide variety of possible applications, this article can present only a small selection of uses.

Since the early days of STM, many different types of SPM (Table 1) have been developed, all of which are based on the same principle: a small probe is brought in close proximity to the surface of a sample in order to measure near-field interaction (Figure 1). In most cases, feedback keeps the interaction strength constant during the passing of the probe across the sample. Scanning is achieved by means of piezoelectric actuators which define the set-up of the probe and sample with an accuracy of the order of a few picometers (10^{-12} m). We are then able to scan a probe across a sample at a distance smaller than the characteristic wavelength of the specific interaction (for STM and the wavelength electrons, this is a fraction of a nanometer, depending on the energy). The so-called near-field interaction regime permits a spatial resolution which is beyond the Abbe limitation.

STM gives us a panorama of conductive surfaces with atomic resolution. SPM has been used in biology, chemistry and physics. In biology, it is valued for its ability to measure in an ambient environment or an ionic solution. It is therefore possible to observe viruses, bacteria or cells in action (e.g. the pulsing of a heart cell) or the interaction between DNA and specific proteins. This cannot be done by using scanning electron microscopy (SEM) or transmission electron microscopy (TEM), because of the need for ultrahigh vacuum (UHV) conditions and/or metal coating. However, the achievable resolution of standard optical microscopy is limited to

Scanning probe microscopy (SPM) has developed to become an integral part of the hierarchy of analytical tools in industrial surroundings, owing to its excellent spatial resolution and its ability to work under ambient conditions. The purpose of this article is to give an insight into the potential of SPM techniques in industrial applications today. Owing to the wide variety of possible applications, this article can present only a small selection of uses.

The given examples highlight typical aspects of the current analytical work of different industrial laboratories. First, an introduction to the specific industry and its analytical obstacles is given. Second, a solution using a SPM method is demonstrated and the particular SPM method is explained in detail. Finally, an actual measurement is given for each example.

To summarize, with the necessary precautions concerning stable conditions during the measurement, SPMs are a useful tool for industrial applications which fulfill the demands of industry today. SPMs are commercially available, rapid, quantitative and reproducible. Furthermore, they are available with a user-friendly interface.

Figure 1 Schematic diagram of an experimental set-up for a typical scanning probe microscope.

0.5 µm and far removed from the atomic resolution available by SPM.

A resolution of better than 1 nm is required for the imaging of almost all chemical processes. SPM has been used to observe rotational and vibrational states of single molecules.\(^9\) It allows the identification of the molecule and a detailed understanding of the chemistry on the nanometer scale. In particular, in the interesting field of the self-assembled monolayer (SAM), SPM has shown great potential.\(^8\) Whereas the self-arrangement of a monolayer of an Au\(_{55}\) cluster can be observed by SEM or TEM, SPM can give additional information about the electronic structure of the cluster (e.g. coulomb blockade and staircase or quantum size effects). SPM allows the observation of the electronic spectra of a single cluster depending on the environment (charge fluctuation).\(^10\) Such investigations are of utmost importance for the use of this cluster for single electron devices and therefore for the future successor of the metal-oxide semiconductor field-effect transistor (MOSFET).\(^11\)

The gate length of this dominant structure of the semiconductor industry of the order of 180 nm today and should break through the 100 nm “frontier” in a couple of years. The semiconductor industry association (SIA) roadmap (a selection is given in Table 3), which represents an agreement with regard to future developments in the semiconductor industry, predicts a gate length of 25 nm by 2015. MOSFETs with a gate length down to 14 nm can be fabricated in the laboratory,\(^12\) but until now not at the mass-production level. Owing to the problems arising from dopant fluctuations or thin-gate dielectrics, we shall need new MOSFET designs with gate length down to 50 nm.\(^13\) These new designs require a precise knowledge of physical properties (e.g. voltage, current or dopant density) at the nanometer length scale. This is exactly the field for SPM application, whereas most
conventional analytical techniques [e.g. secondary ion mass spectrometry (SIMS)] fail at a resolution below 100 nm.\(^{14}\)

Besides high spatial lateral resolution and operation under environmental conditions, there are normally some additional demands required for an industrial application: commercial availability; user-friendly interface; rapidity; quantitativeness; and reproducibility. These points will be discussed in detail in the following sections.

Most common SPMs for industrial application are commercially available from an increasing number of companies (Table 2) in a price range from US$ < 50,000 for laboratories to several million dollars for operation in clean-room conditions and production.

These commercial SPMs are provided with a user-friendly interface that permits a rapid acquaintance with the new tool. A “plug and measure” approach is possible for each user today. However, the main problem is interpreting and understanding the images.

SPMs are a time-consuming analytical tool owing to the small scan range (100 µm) and the relatively slow scanning speed of around 1 Hz per line. An image with a resolution of 512 × 512 pixels takes roughly 8 min. Some developments will produce arrays of cantilevers (e.g. 32 × 32 = 1024 cantilevers) or high-speed cantilevers, which should permit scan speeds of several meters per second.\(^{15,16}\) However, SPM has to be used within a hierarchy of analytical tools. No single instrument can give a complete set of data for a sample. There are without doubt faster analytical tools (albeit with a poor spatial resolution) which can be used to examine whole samples before going into detail into specific areas of the sample by means of SPM. For example, in failure analysis in the semiconductor industry, a first step is to localize failure by means of conventional electrical measurements. This localizes failure to an area of tens of micrometers. In a second step, one can use analytical tools for the evaluation of the physical failure, and by involving computer-aided test stands, the area can be automatically scanned by SPM. At this level, SPM can be used in product monitoring. An increasing number of SPMs are being used in mass production conditions. Most are used to monitor topographic features from particular areas of interest of a wafer of semiconductor devices. Consequently, slow scan rates are no longer a handicap.

Quantitativeness and reproducibility are based on identical circumstances. Both require stable conditions for the probe and sample. The probe (in the case of a topographical measurement of a cantilever) suffers from wear between the apex of the cantilever tip and the samples, which in normal application in the semiconductor industry are extremely hard materials (e.g. silicon dioxide or silicon nitride). A change of the tip shape may lead to a change of the SPM response because the measured topography is a convolution between tip and sample. Knowledge of the tip shape can be gained from calibration structures or SEM measurements and allows the calculation of the “real” topography of the sample. However, a change of the tip shape during the measurement causes problems. This leads to the demand for new materials for cantilevers, e.g. diamond.

In the above-mentioned automated test stand, the tip shape is also controlled automatically between a pair of measurements. A deviation from a certain value leads to an exchange of the cantilever and, as a consequence, tip wear is no longer a problem. More difficult to achieve are stable conditions for the sample. The setting out of an instruction manual for a definable sample preparation is the first step to overcome this problem. Further, the ambient conditions must be taken into consideration, because a change of the relative humidity could lead to different results of SPM measurements on the same sample. The measurement of electrical, thermal or tribological properties depends on the thickness and the properties (e.g. conductivity) of the water layer of the sample. Defined conditions can be realized by placing the SPM in a glove box or flow box with an atmosphere of nitrogen or argon, which permits reproducible measurements, the basis for quantitative results. Furthermore, in almost all cases, a test sample is used to calibrate the probe. For some SPM techniques the measured data (e.g. voltage) must be converted into another physical property (e.g. dopant density).

This conversion requires a detailed understanding of the phenomena on the nanometer scale, and especially the interaction of the probe and sample. The near-field regime gives us resolution that is no longer limited by diffraction, but by geometrical properties (e.g. effective probing area). These properties have to be taken into account to obtain a model for the response of the SPM. The regime, sometimes called the regime of mesoscopic physics, brings together the physics of the bulk material (macro) with the physics of atoms and molecules (micro) and is, although of great interest, not completely understood today. The modeling of the tip–sample interaction may therefore be complicated. Nevertheless, by using some simplifications, one can obtain a useful model for a first conversion with estimable failure. For some types of SPMs, e.g. STM or SFM, there are theoretical models that fit the experimental results very well. Other types suffer from a short lifetime and/or complexity, but improvements are in progress. For a great number of industrial applications, the operator has to distinguish between good and bad samples. This can be done by using SPMs in a more qualitative way.

Finally, with the necessary caution concerning the aforementioned conditions, SPMs are a useful tool for industrial applications which fulfill the demands of the industry today. SPMs are commercially available, rapid, quantitative and reproducible. Furthermore, they are available with a user-friendly interface. The increasing number of companies that are using SPMs in the laboratory and manufacturing every day provides evidence of the rising popularity of SPM.

2 EXAMPLES OF INDUSTRIAL APPLICATIONS OF SCANNING PROBE MICROSCOPY

The following examples highlight typical aspects of the analytical work of different industrial laboratories today. First, an introduction to the specific industry and its analytical obstacles is given. Second, a solution using a SPM method is demonstrated and the particular SPM method is explained in detail. Finally, an actual measurement is given for each example.

2.1 Scanning Force Microscopy of Hair

There is a large market centered around human and animal (e.g. lamb’s wool) hair. Additionally, there are a large number of companies in the cosmetic and textile industries who deal with products for the treatment of hair. Consequently, a detailed understanding of hair and the influences of the products concerning the treatment of hair is the foundation of a market leader. In the past, investigation of hair was done by SEM, TEM and optical microscopy. SEM and TEM require high-vacuum conditions and/or a metallic coating of the specimen. That means that it is not possible to observe the same area of interest of a hair before and after the treatment. Optical microscopy, however, lacks a suitable resolution. Only SPM combines the possibility of working in environmental conditions with appropriate resolution. Furthermore, it enables an in situ study of the processes during the treatment of the hair.

To measure the topography of an insulating surface, a SFM is used. The probe, in this type of SPM, is a small cantilever with a sharp needle at the end. The cantilever is brought in close proximity to the sample, so that the tip of the needle touches the surface and the cantilever is bent out of shape for repulsive mode imaging. Imaging can also be done in the attractive mode, where deflection of the tip toward the surface by dispersion or other forces is measured. The deflection of the cantilever perpendicular to the sample is measured, (in all commercial SFMs) by an optical method. Feedback keeps the deflection constant during the movement of the tip across the sample, by means of a piezo actuator. This mode is called the constant force mode, because a constant deflection of the cantilever results in a constant force between the probe and sample. With the implementation of microfabricated silicon or silicon nitride cantilevers (with spring constants of the order of 0.01–1000 N m⁻¹) and an optimized optical detection system, a cantilever deflection ranging from 0.01 nm to a few micrometers can be detected. This corresponds to forces between 10⁻¹³ and 10⁻¹² N. Cantilevers with spring constants of 0.01–1 N m⁻¹ are used in the contact mode, where the tip remains in contact with the sample during the entire measurement. An investigation under ambient conditions produces a water layer at the sample, which induces a large attractive force (capillary force) between tip and sample. As a result, the minimum possible force that can be used for SFM in air is of the order of 10⁻⁹ N. Even for such small forces, some structures of soft samples, e.g. biological samples, could be destroyed. In such cases, an intermittent mode, or so-called Tapping Mode™, can be used, where the cantilever touches the surface with a frequency near to the resonant frequency of the cantilever. Typically, the resonant frequency is in the range 50–500 kHz, corresponding to values of the spring constant of the cantilever of 1–50 N m⁻¹, with an amplitude of 10 nm. By using the Tapping Mode™, minimal loading forces of 10⁻¹² N can be realized. Hence the Tapping Mode™ is the most popular mode for the investigation of biological samples in air or in liquids. In the following, some examples are given for the analysis of human hair.
A special problem concerning products for the treatment of hair is the existence of many different phases of the hair, depending for example on the length, which correlates with the age of the fragment of a specific hair. Close to the root, i.e. young hair (Figure 2a), the edges of the cuticle cells are smoother than for older ones (Figure 2b). Near the tip (Figure 2c) of the specific hair under investigation with a length of 45 cm and an age of about 3 years, almost all cuticle cells are broken away and the cortex of the hair can be seen. It is therefore apparent that any investigation of the effects of a treatment must be realized by the observation of the same area of the same hair. An example is given in Figure 3(a) and (b), which shows the same area before and after a bleaching process. Parts of the cuticle cells are broken away owing to the oxidation process.

The results shown cannot be achieved merely by using SEM or TEM; rather, they can only be achieved by using a larger set of samples and SEM or TEM combined with statistical evaluation methods. Therefore, alternative analytical tools are more time-consuming, and it can be seen that for in situ analysis, there is no alternative to SPM today.

These results demonstrate the value of SFM as an analytical instrument within the cosmetic and textile industry.

2.2 Magnetic Force Microscopy of Tapes

Hard disk capacity is increasing more rapidly while the physical size decreases, owing to the shrinking of the bit size. The magnetic structure of current commercial devices (which represents the physical unit of the information) is of the order of some 100 nm. This structure has to be written and read with a frequency of more than 100 MHz, which places great demands on the recording
head. The immense market for storage devices, together with intense competition, force technology to produce higher data densities and transfer rates. A technological advantage can always be seen as an advantage in terms of competition.

The only analytical method for the investigation of magnetic structures of less than 1µm in industrial surroundings is MFM. All other methods such as electron holography, superconducting quantum interference device (SQUID), Hall bar and TEM suffer because of extraordinary sample preparation methods and/or lack of the appropriate resolution. There have been some developments to fabricate ultrasmall SQUID and Hall bar magnetometers and electromagnetic force coils on the top of a cantilever, but they remain commercially unavailable so far.

MFM is based on SFM (which is outlined in detail in section 2.1). It permits the measurement of the stray field of a magnetic structure with a spatial resolution of <50 nm. All MFM realizations measure either the force itself or the force gradient between a magnetic tip and the sample. Most of the commercial tips for MFM are silicon cantilevers with a thin magnetic coating such as cobalt, iron or nickel. A common MFM mode is the so-called “lift mode”, which permits the virtually simultaneous measurements of the topography and the magnetic stray field of a sample. Most true noncontact methods show a mixture of topography and magnetic signal. To overcome this disadvantage, we need an independent measurement of both quantities. In the lift mode (Figure 4), initially, the cantilever measures the topography for one scan line and stores the information. The tip is then raised 30–60 nm and the stored data are used to retrace the topography, but vertically displaced. A deflection of the cantilever in the second scan line is an effect of a long-range interaction such as a magnetostatic field and is interpreted as the magnetic signal in MFM. By using a nonmagnetic tip, the deflection signal can be explained by electrostatic interaction. In MFM, the influence of an electrostatic field is avoided by the grounding of the tip and cantilever. In comparison with other SPM methods, the resulting data reflect the interaction of a small probe and a sample. A strong magnetic field from the tip can destroy a soft magnetic sample such as garnet films or permalloy, whereas a strong magnetic field from a sample can change the direction of the magnetization of the tip, which leads to a serious disturbance in the measurement. Therefore, it is important to make the right choice for the type of magnetic tip for a particular sample. For a successful interpretation of a MFM image, it is vital to know the precise magnetization of the tip. This can be done by using a calibration structure, such as a hard disk with a well-known magnetic arrangement.

MFM allows the direct observation of recording heads in operation with frequencies up to and even beyond 1 GHz. However, the resulting structure, which was written by using recording heads, is the subject of many investigations concerning hard disks and any other magnetic storage devices. Figure 5 shows the topography and magnetic signal of a magnetic tape written with 6 MHz. A comparison of different tapes (not shown here) which were written with different parameters allows a check of the performance of the specific configuration.

Another industrial application is the use of MFM for measuring the current of a specific point on an integrated circuit (IC). Owing to the increasing integration of devices in IC fabrication, there is an equally increasing urgency to measure currents of a few hundred microamps with a lateral resolution of <100 nm. Hence some effort is being put into the use of MFM as a standard tool for failure analysis within the semiconductor industry. Here, quantitative results concerning the current of a specific wire are needed. This can be realized by using a calibration standard for the evaluation of the magnetic structure of the tip and an algorithm to convert the measured data into current values considering the specific geometrical properties of the sample.

To summarize, MFM is a widespread technique within the magnetic storage industry, and is also being used within the semiconductor industry.

2.3 Scanning Thermal Microscopy of Hot Spots

The global semiconductor market has doubled with every second generation of technology. Business with ICs is more strongly linked with technological progress than in any other market. Worldwide market forces drive manufacturers to produce ever more highly integrated
products, from the very large-scale integrated (VLSI) towards the ultralarge-scale integrated (ULSI) IC generation. This lays the foundation for the amazing law of Moore, which predicts that the numbers of transistors on an IC quadruples every 3 years. The degree of integration leads (besides the shrinking size of the unit devices) to thermal problems concerning local heat sources on an IC: so-called hot spots. A sophisticated design may avoid these hot spots, but it is an important requirement to be able to detect them with a lateral resolution of less than a few hundred nanometers. A standard tool in failure analysis for the localization of hot spots is liquid-crystal thermography (LCT). By means of thermal activation of the liquid crystal, it is possible to detect hot spots by optical microscopy. The radiation of hot electrons can be determined by emission microscopy (EM) or rather spectroscopic photon emission microscopy (SPEM). Thus the thermal effects of leakage currents in gate oxides can be measured. Both techniques (EM and SPEM) have a maximum spatial resolution of 0.5 μm. For higher magnification, SThM must be used.\(^{(32,33)}\)

Useful SThM for the semiconductor industry combines SFM (see section 2.1) with a highly sensitive thermal detector at the end of the cantilever.\(^{(32,33)}\) Detectors based on thermocouples, Schottky diodes and resistors have been developed. Figure 6(a–c) shows an schematic set-up of an SThM which is based on the measurement of a resistor consisting of a Wollaston wire with a platinum core. The wire is used as a cantilever to measure simultaneously the topography and the thermal properties of the sample. By applying a small current, the temperature distribution can be measured. Figure 7(a) and (b) shows a SThM measurement of an \(n\)-channel MOSFET operating in breakdown. A relative increase of the temperature (of the order of 1 K) can be determined close to the gate below the drain, where we can receive no signal by using SPEM, because of the shielding of the metallic drain contact.

A larger current can be used to probe the local thermal conductivity. A calibration process permits a quantitative determination of this value (in \(W \cdot cm^{-1} \cdot K^{-1}\)) with a spatial resolution of \(<1 \mu m\).\(^{(34)}\) This gives the ability to track down defects which are covered by a passivation layer.

Finally, SThM gives us a chance to detect defects from the rear side of a thinned sample. This can be a great advantage for the use of SThM in failure analysis owing to the tendency for an increasing number of layers above the actual devices.

2.4 Kelvin Force Microscopy of Metals

The steel industry is sometimes thought to be outdated. Nevertheless, it is one of the biggest markets today. Metallurgy is a very important science for heavy industry. One of the most important areas of metallurgy is the investigation of corrosion. Because corrosion is well described by the surface potential, it can be measured by KFM\(^{(35-37)}\) with a spatial resolution of <100 nm. Conventional techniques cannot be used in air or they suffer from poor lateral resolution.

This derivative of SFM is based on the lift mode, which was explained in section 2.2. A first scan gives us the topographical data and the second scan, at a defined scan height above the sample, gives us information about the long-range interaction. In the case of a non-magnetic metal, this is the electrostatic field between the sample and the metallic tip. A quantitative value is reached by applying a voltage to the tip which is composed of a direct current (DC) and an alternating current (AC) part. The frequency of the AC part is near the resonant frequency of the cantilever, which allows an extremely sensitive measurement. By measuring the first harmonic oscillation of the deflection signal of the cantilever by a lock-in amplifier, it is possible to balance this signal to zero because of an adjustment of the DC voltage (see Figure 8). This means that the applied DC voltage equals the reversed surface potential. Hence KFM produces a two-dimensional (2-D) map of quantitative values for the surface potential and the topography with a spatial resolution of <100 nm. By using a UHV/KFM system, it is possible to observe single dopant atoms.\(^{(38)}\) On the other hand, the measurement is based on the long-range interaction between tip and sample, therefore each point probing is an average. Only 50% of the measured forces can be located within a region with a radius of 100 nm underneath the tip, depending on the tip shape. Hence KFM gives a high spatial resolution, but the value of the measured structure depends for small structures (<100 nm) on the size and the value of the surface potential of the surrounding.

Nevertheless, KFM is an advantageous tool for the analysis of corrosion.\(^{(39)}\) KFM allows a time-dependent study of the process of corrosion in air or in a specific solution, such as salt water.

![Figure 8 Schematic diagram of an experimental set-up for KFM and useful equations concerning the measured signal.](image-url)
SCANNING PROBE MICROSCOPY, INDUSTRIAL APPLICATIONS OF

Figure 9 20 × 20 µm images [(a) topography and (b) corresponding surface potential map] of a metallic foil.

In addition to corrosion, the local detection of the accumulation of elements, which results from a separation process of an alloy, is also an important area in metallurgy that can be investigated with KFM. An extreme treatment of metal, such as rolling it to a foil, can lead to significant modifications of the surface and, furthermore, to a modification of the properties of the metal in an electrochemical environment. Figure 9(a) and (b) shows the results of a KFM measurement of a metallic foil. The dots of the surface potential image seem to be accumulations of lead and can be located at the maxima in the topography. This can be a meaningful hint for the optimization of the treatment process.

To summarize, KFM can be used as an analytical tool in metallurgy and combines the possibility of in situ measurements with a high lateral resolution.

2.5 Scanning Capacitance Microscopy and Scanning Spreading Resistance Profiling of Dopants

Following the comments above, the semiconductor market is growing exponentially and requires technological progress. To acquire a feeling for the direction of this progress and to coordinate the research, the SIA created the National Technology Roadmap for Semiconductors (NTRS), which brings into focus the required progress over the next 15 years (Table 3).40 A consequence of the NTRS is the need for an analytical tool for the assessment of 2-D dopant profiles with a spatial resolution of <10 nm. It is an urgent requirement to calibrate technology computer-aided design (TCAD) process simulators for future chip design. The failure analysis of semiconductor devices requires analytical tools with a spatial resolution of <50 nm today.

Lateral SIMS suffers from the necessity to design and prepare a special sample geometry. ‘Selective etching’ combined with SEM or TEM is lacking for quantification. Both methods need UHV conditions and are destructive procedures. A further candidate, electron holography, suffers from a large-scale sample preparation method and a low sensitivity concerning the doping concentration. Finally, the most promising tools are SCM (Figure 10)41–44 and SSRP (Figure 11).45–49 The above-mentioned KFM can also be used for 2-D dopant profiling,50 but KFM is very sensitive to surface contamination and lacks the required lateral resolution. KFM imaging is a weighted averaging over the sample, due to the measured long-range electrostatic interaction between the tip and sample. Figure 12(a) and (b) shows a KFM measurement in comparison with an SCM measurement on the same sample.

SCM and SSRP are based on SFM operating in constant-force and contact mode (for details see section 2.1). Both instruments need conductive

cantilevers to connect the apex of the tip with a special detector. The SCM sensor allows the detection of a capacitance of \( <1 \text{ aF} \) \((10^{-16} \text{ pF})\). The probing voltage has a frequency of 915 MHz and a typical amplitude of 2 V. To reduce the influence of stray capacitance, we adopt a lock-in technique to produce a signal that is proportional to \( dC/dV \). Like conventional capacitance–voltage measurements, the capacitance measurements by means of an SCM depend on the doping concentration. The probing voltage results in a change of the depletion region underneath the tip. Therefore, the spatial resolution depends on the doping concentration and on the tip shape, or rather the radius of the area of the tip which is in direct contact with the sample. Simulations, which are carried out by a device simulator (DESSIS\textsuperscript{\textregistered}), indicate a spatial resolution of \(<20 \text{ nm}\). By using the right sample preparation method in combination with the right tip, it should be possible to achieve this resolution experimentally. For an SCM measurement, silicon cantilevers with a metallic coating are used. One may utilize any other conductive cantilever, e.g. (doped) silicon or (doped) diamond cantilevers, but the influence of the doped probes, concerning the depletion region into the apex of the probe, must be taken into account.

Unlike SCM, SSRP needs extremely hard probes, such as doped diamond cantilevers. The resistance between the tip and the back contact of the sample is measured by means of a logarithmic amplifier. The potential spatial resolution of \(<20 \text{ nm}\) results from the measurement of the spreading resistance. This is the resistance directly underneath the tip–sample contact and requires an ohmic contact between the tip and sample. By the pressure of the cantilever against the silicon probe, the native oxide is penetrated. At a pressure of 10 GPa, it is possible to obtain an ohmic contact. This necessary high pressure is crucial to SSRP. With the utmost caution concerning the contact force, a doped-diamond cantilever can be used for one or two measurements. Figure 13(a) and (b) gives an SCM and an SSRP image of the same sample.

Both methods need extremely smooth samples, with a roughness of \(<0.3 \text{ nm}\) (RMS). Whereas the cantilever is crucial to SSRP, in SCM it is the requirement for a thin oxide layer. This layer must be of high quality, with a thickness of the order of 3 nm, and it must be produced by a low-temperature process to avoid diffusion of the dopants. Owing to the application of such thin oxides for future MOSFETs, there are many investigations concerning the production process, but they are not yet adequately understood. However, by applying small values of the DC voltage of no more than 1 V, the native oxide can be used for SCM measurements.

TCAD systems and each operator need the values of the local doping concentration, whereas SSRP and SCM measure the local carrier concentration and give
Figure 13 A line scan of the same location of a test structure by (a) SSRP and (b) SCM [above, measured signal; below (shaded gray), assumed dopant concentration]. Both methods show great potential for 2-D dopant profiling.

a signal that is related to the spreading resistance and the capacitance, respectively. Therefore, the measured value must be converted into the doping concentration. Normally (besides a calibration procedure for each tip) the conversion is done by means of a look-up table. At the moment, it works only for one-dimensional (1-D) doping profiles, but some efforts are going into the conversion of 2-D profiles.

Figure 14 shows a SCM image of a cross-section of a DRAM, prepared by a lift-off procedure. Whereas the topography shows the remainder above the transistor structures, the capacitance image locates the different dopant concentrations (n-Si light, p-Si dark).

To summarize, SCM and SSRP can be used to advantage in semiconductor failure analysis today.

2.6 Conducting Atomic Force Microscopy of Oxides

The above-mentioned NTRS predicts a gate oxide thickness of <5 nm for the next generation of ICs. A simple extrapolation of the 250 nm MOSFET design to the 25 nm generation would suggest a gate oxide thickness of 0.5 nm, which means that it consists of two monolayers and the device will not be viable. Therefore, we need new designs and/or new gate oxide materials. These confirm the significance of a method for the investigation of thin oxides with a spatial resolution of <10 nm. Today, oxide thinning due to the local oxidation of silicon (LOCOS) process can lead to a leakage current. The observation of a cross-section, by means of TEM, can show us only part of the whole LOCOS boundary. On the other hand, SPEM suffers from a deficient resolution.

Today, c-AFM is the best choice for the characterization of thin oxides. It is based on the SFM (see section 2.1) and the well-known Fowler–Nordheim (FN) tunneling process (see Figure 15). The current through the oxide can be measured with a noise level of <20 fA. A fit of the measured current–voltage curve, using the FN equation, gives the required thickness of the oxide with
a resolution of <0.5 nm. This simple approach requires a homogeneous, high-quality oxide. Interfacial traps and impurities in the oxide can change the current significantly. The sensitivity to the oxide quality determines c-AFM as a useful tool in the failure analysis of semiconductor devices. For oxides, with a thickness of <20 nm, a spatial resolution of <10 nm can be achieved, owing to the exponential nature of the FN current. Crucial to this technique is the tip. It has to be able to conduct, and must be as sharp and as hard as possible, because of the great forces of the high electrical fields between the tip and sample. The best choice is a doped-diamond cantilever, sharpened by a focused-ion beam (FIB) system.

Figure 16 shows an analysis of the tunneling-gate oxide (TOX) of an electrically erasable programmable read-only memory (EEPROM). The measurement was carried out by a bias voltage of 10 V and gives us as a result the thickness of the oxide (of the order of 8.5 nm for TOX and 50 nm for field oxide (FOX)), and the quality of the oxide, which refers to an excellent oxidation process.

Finally, c-AFM gives us significant hints concerning the analysis of thin oxides, because of its high spatial resolution with regard to the thickness and quality of an oxide.

3 PERSPECTIVE AND FUTURE DEVELOPMENTS

All above-mentioned SPM methods reach a spatial resolution of <100 nm and are able to operate in air. The majority of them can also be used in almost any liquid. The difficulties concerning the demands for an analytical tool in an industrial environment are commercial availability, user-friendly interface, rapidity, quantitativeness and reproducibility. They are highlighted in section 1.

Further progress must be made in combining different SPM methods, an automatic calibration procedure for an actual probe and the development of specific probes. These points will be explained in detail in the following.

Figure 17 gives as an example an overview of possible SPM methods for operating in failure analysis in the semiconductor industry. Today, all methods are commercially available, but difficult to combine. For example, the combination of SCM and c-AFM seems to be very useful for the analysis of semiconductor devices. Whereas SCM is less sensitive to the oxide thickness and extremely sensitive to the dopant concentration, c-AFM shows the opposite behavior. Therefore, a combination would appear to be a great advantage. An automatic procedure for the calibration of the actual probe would be another worthy goal. These are challenges for all SPM researchers.

Another key issue for SPMs today is the development of special probes. Because of the large number of new innovative features added to the third generation of SPM
methods, following on from the work on STM and SFM, not all special probes are commercially available. This is a challenge for all researchers working on SPM probe development.

Finally, the main goal is a multifunctional SPM system combined with an expert system to give appropriate guidelines concerning the interpretation or quantification of the resulting measurements for each operator in an industrial setting. This requires the cooperation of researchers of SPMs, inventors and users in the universities and industrial companies, and some efforts are now being made in this direction. SPM has developed to become an integral part of the hierarchy of analytical tools in industrial settings, which may be due, in part, to its excellent spatial resolution and its ability to work under ambient conditions.

ACKNOWLEDGMENTS

It is a pleasure to thank G. Fiege (SThM), A. Kelch (SFM) and A. Olbrich (c-AFM) for supplying SPM images. Moreover, I acknowledge the SXM group at the University of Hamburg, who provided assistance and support.

Scanning tunneling microscopy (STM), scanning tunneling spectroscopy (STS) and related techniques with their unique capability to resolve topological and electronic structures at atomic level have revolutionized the power of experimental techniques in high resolution imaging of surfaces. In STM, a sharp conducting tip is mechanically scanned over a conducting or semi-conducting sample at the distance of few angstroms from the surface. A voltage bias applied between the tip and the sample leads to flow of tunnel current, which decreases exponentially as the gap increases. By keeping the tunnel current constant with an electronic feedback controller the tip is maintained at a fixed distance during the scanning by means of a 3-D scanner made of a piezoelectric transducer. The trajectory of the tip then traces out a profile of the surface, including the bumps due to individual atoms. In the context of atomic resolution imaging capability, there are only a few techniques such as scanning transmission electron microscopy (STEM), transmission electron microscopy (TEM) and field ion microscopy (FIM) which perform as well as STM, but they do so under extremely special circumstances. The traditional spectroscopic techniques that can be compared with STS are those of conventional (elastic) electron tunneling spectroscopy (ETS) and inelastic electron tunneling spectroscopy (IETS), X-ray photoelectron spectroscopy (XPS), ultraviolet photoemission spectroscopy (UPS) and inverse photoemission spectroscopy (IPS). But all these techniques detect and average the data from a relatively large area, a few microns to a few millimeters across. The STM/STS, in contrast, can take spectra localized to as small an area as an individual atom. The most important characteristic that distinguishes STM/STS from other techniques is ability to operate in a variety of different environments such as air, reactive gases, liquids, electrolytes and biological fluids, leading to its applications not only in basic research in surface science but also in such diverse fields as lithography, electrochemistry, biology and medicine. An inherent limitation of STM is that it always operates at high resolution and, therefore, works better for atomically flat surfaces.

1 INTRODUCTION

Surface studies are of intrinsic interest because most solids interact with the external environment through their surfaces; they are also important in a large number of phenomena of great technological importance. Traditionally, surfaces have been studied by conventional techniques such as TEM, scanning electron microscopy (SEM), low energy electron diffraction (LEED), reflection electron microscopy (REM), X-ray diffrac-
tunneling and scattering experiments, and field electron microscopy (FEM) and field ion microscopy (FIM). STM, with its unique capability to resolve topographic and electronic structures at atomic level in vacuum, atmospheric and fluid environments, has removed the limitations of some earlier techniques and revolutionized the experimental techniques not only in basic research in surface science but also in applied research in such diverse fields as lithography, electrochemistry, metrology, tribology, biology and medicine.

2 HISTORY

The first glimpse of the STM concept appeared in the 1970s in the form of an instrument called “topographiner” based on the principle of the scanning field emission microscope. Although it was recognized that atomic resolution could be achieved by improving the tip, precision and stability of the instrument, it was not experimentally realized until 1982, when a group at IBM, Zürich, observed that the tunnel conductivity plots on surfaces involved sharp repeated steps and faint bumps of atomic dimensions. Although the origin of STM can be traced back to the early 1980s, it came into the limelight only after the announcement of the Nobel Prize to its inventors, G. Binnig and H. Rohrer in 1986, which led to an outburst of worldwide interest. In recent years, STM activity has grown beyond the original expectations, leading to a totally new branch called scanning probe microscopy (SPM), which has established itself as an indispensable tool in the realm of materials science and microelectronics. Several historical overviews can be cited for an absorbing account of the invention and development of STM and related techniques.

3 SCANNING TUNNELING MICROSCOPY/SPECTROSCOPY: BASIC PRINCIPLES

3.1 Phenomenon of Tunneling

According to quantum mechanics, a subatomic particle can pass through a spatial region in which the particle’s kinetic energy is less than its potential energy. The phenomenon is known as tunneling. Figure 1 shows an energy diagram for a typical tunneling process. The observation of the tunneling effect in a variety of systems has offered direct evidence of quantum mechanics in action. Some of the landmarks in the science of tunneling are: observation of field emission from metal, ionization of hydrogen atoms by electron tunneling, explanation of field emission, alpha particle decay process in heavy atoms, the development of FEM and FIM in the degenerate p–n junction, experimental verification of Josephson effects (tunneling Cooper pairs), IETS, the development of the topographiner and STM.

3.2 Theory and Operation of Scanning Tunneling Microscope

As the name suggests, STM makes use of the phenomenon of tunneling discussed in the preceding section; according to this, if two metals are brought close enough, i.e. they are separated by only a few angstroms, the wave functions of electronic quantum states of the two surfaces overlap. The overlap allows electrons to jump across the vacuum gap between the tip and the sample, leading to a tunnel current when the voltage is applied between them. The tunneling current expression for low bias based on the free electron model is as stated in Equation (1) below:

\[ J = \frac{3}{4\pi} \frac{e^2}{\hbar} V \frac{k_0}{s} \exp(-2k_0s) \]

where the \( V \) is applied voltage, \( s \) is the barrier width and \( k_0 \) is the decay constant of the wave function in the barrier (\( \hbar k_0^2/2m = \phi \), the work function). This expression indicates that \( I \propto V/s \exp(-A/\phi^{1/2}x) \), if \( V \) is in volts, \( s \) in nm, the average work function \( \phi \) in eV, then \( A = 10.25 \text{ (nm)}^{-1} \text{ eV}^{1/2} \). The exponential dependence was measured by Young et al. and Teague and later by Binnig et al. The main feature of this equation is its extreme sensitivity of tunnel current to changes in \( s \). A change of electrode spacing of 0.1 nm produces approximately an order of magnitude change in current for a barrier height of 5 eV. In STM (Figure 2), a metal wire (called a tip), with a finely ground or electrochemically etched point, is positioned near the sample surface to be investigated so that a measurable tunnel current (nA to pA) flows for a reasonable bias voltage (a few millivolts to several volts). The tip is then mechanically scanned across the sample surface by
means of a 3-D scanner made of piezoelectric transducers. If the surface is rough even at atomic level, the tunnel current will change with the tip location on the surface. The voltage at z-piezo required to maintain the current constant as a function of \( x, y \) coordinates derived from voltages at \( x- \) and \( y- \) piezos yields a topographic profile of the surface.

### 3.3 Resolution and Magnification

There are no special resolution criteria in STM. The vertical resolution is governed by the stability of the tunnel junction, since height details of the sample surface smaller than the tip to sample vibration amplitudes are usually masked. The lateral resolution is determined by the width of the tunnel current. The approximate expression for tunnel current \( I \propto V \exp(-2k_0s) \) can be used to get an order of magnitude estimate of the vertical and horizontal resolution. In Figure 3, at a given lateral position \( \delta/2 \) relative to the center of the tip, the height of the corresponding point on the tip is \( z = s + \delta^2/8R \), assuming a curved tip of radius of curvature \( R \) and distance of closest approach \( s \). Thus the current has a Gaussian profile, with root-mean-square width \( 2(R/k_0)^{1/2} \). Since \( 2k_0 \approx 1 \text{Å}^{-1} \) (10 nm\(^{-1} \)), the lateral resolution of \( L = 50 \text{Å} \) (5 nm) can be estimated for a typical smoothed field emission tip of ca. 1000 Å (100 nm). The estimation of resolution can be improved by preparing ultra-sharp tips by a factor of 2, but is still smaller than atomic resolution. It turns out that most of the chemically etched or mechanically ground tips have asperities of near atomic dimensions and because of the strong dependence of tunnel current on distance only asperities closest to the sample will contribute substantially to the tunnel current. It is clear that atomic resolution would require atomically sharp asperities. More elaborate estimation of lateral resolution based on quantum mechanical calculation yields \( L_{\text{eff}} = 1.66[(s + R)/k_0]^{1/2} \). The actual resolution can be smaller than this if the apex of the tip has an atom with a directed orbital pointing outwards. It appears that\(^{36,37} \) p-orbital type of element of elemental semiconductors or d-orbital from d-band metals such as tungsten, etc. are favorable for atomic resolution on metal surfaces.

### 3.4 Imaging Modes

There are two main modes of STM-imaging: constant height mode and constant current mode.

#### 3.4.1 Constant Height Mode

A straightforward application of Equation (1) for imaging would involve scanning the tip at constant height for a fixed bias across the tunnel junction and monitoring the tunnel current either on the oscilloscope or via a video-processor. The method is therefore called current imaging. This has an obvious advantage that relatively high speeds (1 kHz) can be used, enabling real-time video display of the surface.\(^{38} \) The disadvantage is that the method can only be used for atomically flat surfaces, where the surface roughness is less than the tunneling gap.

#### 3.4.2 Constant Current Mode

This is the most widely used method for acquiring STM images. As in the previous method, the tip is scanned across the surface at constant voltage. However, the time-constant of the servo-system is selected to maintain the tunnel current, hence the height of the tip above the surface is kept constant by changing the voltage to the z-piezo. The feedback voltage for z-piezo, which is proportional to the z-displacement of the tip, is recorded as a function of \( x, y \) coordinates of the tip and therefore generates a topographical image of the surface. The constant current topography maps the local density of states (LDOS) at the position of the tip.\(^{39,40} \) The scan rate in this method is typically low (<10 Hz) and is limited by the response time of the feedback loop and the inertia of the motion.
According to Equation (1) the current is a measure of topography (distance-dependence) only if work function $\phi$ and pre-factor are constant over the scanned area. If both $\phi$ and $s$ vary, the STM-image would involve convolution of topographic and electronic information. In such cases it is possible to record barrier electronic by plotting $\partial \ln I/\partial s$ instead of $I$. The comparison of two images facilitates extraction of topographic information.\textsuperscript{(22–27)}

### 3.5 Fundamentals of Tunneling Spectroscopy

The tunneling expression used for understanding STM operation in the previous sections was derived by assuming low bias voltage, implying that the electron current was coming essentially from a small band of electron states near Fermi-energy.

If the applied voltages are large compared with the Fermi-energy, the resulting image may depend dramatically on the bias voltage, and the approximate tunnel current expression for nonzero voltage $V$ between tip and sample can be written as\textsuperscript{(41)}

$$I \propto e^V \rho_1(E) \rho_2(E - eV) T(E, V) dE$$ \hspace{1cm} (2)

where $\rho_1(E)$ and $\rho_2(E - eV)$ are the surface state densities of sample and tip respectively at energies relative to their Fermi-levels and $T(E, V)$ is the transmission term for tunneling electrons.

In WKB approximation, the maximum transmission has the form shown in Equation (3):

$$T_{\text{max}}(E, V) = \exp\left\{-2s \frac{2m}{\hbar^2} \phi - \frac{|eV|}{2} \right\}$$ \hspace{1cm} (3)

For a small bias this reverts to Equation (1). It can be seen that the tunnel current varies by about an order of magnitude for a unit change in bias voltage. As the dominant contribution of tunneling current comes from states near the Fermi-level of a negatively biased electrode, tunneling from tip to sample mainly probes empty states of the sample, with negligible influence from the occupied states of the tip, whereas the tunneling from sample to tip is much more sensitive to the electronic structure of empty states of tip, which often prevents detailed spectroscopic STM studies of the occupied states of the sample.

There are three modes in which to perform tunneling spectroscopy: constant current mode, constant separation mode and current imaging tunneling spectroscopy (CITS).

#### 3.5.1 Constant Current Mode

The simplest way of obtaining spectroscopic information is to compare constant current topological images acquired in the conventional constant current mode at different bias voltages. If the electrons tunnel from sample to tip (negative sample bias), the occupied (bonding) states of the sample are imaged. If they tunnel from tip to sample (positive sample bias), the empty (antibonding) states appear. To obtain qualitative information, a high-frequency sinusoidal modulation voltage can be superimposed on the constant bias voltage between tip and sample. The modulation frequency is chosen to be higher than the cut-off frequency of the feedback loop, which maintains a constant tunneling current. By recording the in-phase component of modulated tunnel current using a lock-in amplifier, a spatially resolved spectroscopy signal $dI/dV$ can be obtained simultaneously with the topographic image.

#### 3.5.2 Constant Separation Mode

The constant current mode based on the modulation technique experiences problems in cases where no current is flowing i.e. at zero bias voltage or in band gap and in cases where the conductivity diverges (metals) as the bias voltage approaches zero. These limitations are overcome in constant separation modes where the tip is temporarily frozen above the fixed height by breaking the feedback circuit for certain time interval using a sample-and-hold circuit while the $I-V$ curves are recorded. The $I-V$ curves are repeated several times at each point and the signal averaged to reduce the noise. The method is particularly useful for probing bandgap states in semiconductors because the small currents which lead to crashing of the tip into the sample are avoided by breaking the feedback action. The plot of normalized differential conductance $(dI/dV)/(I/V)$ versus the bias voltage mimics the density of states spectrum. The agreement with theoretical density of states can be expected only for the positions of the peak as the intensities may differ significantly.

#### 3.5.3 Current Imaging Tunneling Spectroscopy

The combination of scanning ability of STM with the spectroscopic capability, i.e. measurement of local $I-V$ curves leads to the third mode of spectroscopy, CITS. In this method, the feedback control circuit used for constant current STM is gated using a sample-and-hold circuit so that it is active for only 20 to 30% of the time. When the feedback is active, a constant voltage that is applied to the sample and feedback control adjusts the tip height to maintain the tunnel current at a constant level. When inactive, the position of the tip is held stationary and the tunnel current is measured at various different bias voltages. By acquiring the $I-V$ curves rapidly as compared to the scan speed of the tip, both the sample “topography” and spatially resolved tunneling characteristics can be
obtained either at each location or at only a few selected locations. The spatial resolution of tunneling spectroscopy is similar to STM and is determined by the size of the probe. The energy resolution is determined by the range of electron energies that can contribute to the tunnel current. Inelastic tunneling spectroscopy, which involves interaction of tunneling electrons with vibrational modes of molecules adsorbed on a surface can be used to obtain a vibrational spectrum of an individual molecule or molecular functional group. At low voltage, the effective energy resolution is \( \approx 5.4 kT \).²²

4 INSTRUMENTATION AND METHODOLOGY

The important components of STM are: STM head, control electronics, tip and sample, vibration and acoustic isolation and data acquisition system.

4.1 Scanning Tunneling Microscopy

The STM head consists of the sample, tip and a 3-D micromanipulator which controls the precision positioning of the tip. The tip must be brought within few angstroms of the sample surface. This is generally done in two steps. The coarse positioning involves bringing the sample towards the probe from a distance of several millimeters to a few hundred angstroms. The fine positioning involves moving the probe from a few hundreds of angstroms to the tunneling distances. Many types of tip approaches have been used, mostly based on piezo fabrications in the form of a “louse”, inertial sliders which move the sample towards the tip by a slip-stick mechanism or by using the bending motion of the piezoelectric tubes.²³–²⁶ A much simpler approach involves use of micrometers or fine pitched screws, whose motion is demagnified by use of differential springs or levers. The fine positioning approach mainly involves tripod structures made up of three piezoelectric bars, whose motion can be independently controlled by applying voltages to individual electrodes or a single tube scanner with segmented electrodes.²⁶ A schematic diagram of a typical STM head is shown in Figure 4.

4.2 Control Electronics

The current from the tunnel junction is converted into voltage by a preamplifier firmly mounted on the STM head to minimize electrical interference. Since the tunnel current is exponentially dependent on distance, the signal is linearized by a logarithmic amplifier to improve the dynamic range. This voltage is given to the input of the feedback controller, which consists of a difference amplifier, an analog integrator with variable time constant, a proportional amplifier, a low pass filter and a voltage driver.²⁷ Figure 5 shows a block diagram of STM instrumentation.

4.3 Data Acquisition, Image Processing and Analysis

The electrical signals from the inputs of \( x \), \( y \), and \( z \) (error signal from feedback) piezos, the tip voltage and tunneling current are stored in an image file on the PC or workstation.²⁸,²⁹ Graphical routines are used to display the data and for image processing. The display usually involves 3-D line plots or a top view gray or color image (Figure 6). Several image-processing techniques can be used to enhance the quality of the data. For instance, the tilt of the sample can be compensated by a background plane subtraction. The image can be corrected for thermal drift and hysteresis. Histogram equalization of gray or color images is possible. Noise reduction is possible by using several filtering techniques such as smoothing, median filtering, sharpening, edge detection and correlation-averaging in the spatial domain or Weiner filtering in the frequency domain. Typical analysis facilities would involve line profiling (cross-sectional view), height-histograms, fast Fourier transform (FFT), roughness data and grain analysis.

4.4 Preparation and Characterization of Tip and Sample

The tip is the most important, yet least understood, part of the STM. The size, shape and chemical identity of the tip all seem to influence the resolution. The tips prepared by chemical etching, mechanical grinding or simply...
cutting at an angle have been found to produce atomic resolution without further treatment. However, such tips may give erratic performance. The most popular method for making STM tips is based on an electrochemical technique which uses tungsten wire of 0.1 mm to 0.5 mm in diameter as a working electrode in an approximately 1 or 2M NaOH or KOH aqueous solution with carbon or stainless steel as a counter electrode. The immersed portion (2–3 mm) of the wire is etched as alternating current (AC) or direct current (DC) is passed through it at typically 5 to 15 V. Because of the preferential etching at the meniscus in the solution, neck formation takes place at the liquid interface. When the neck becomes very thin it can no longer support the lower portion, which eventually falls off due to brittle fracture. The etching is stopped at this point by an electronic control circuit, which senses the change in the etching current when the etched lower portion of the wire drops down to avoid further electrochemical reactions. The tips are then washed in distilled water, and are ready for use.\(^{50}\)

The AC etched tips tend to have larger cone angles than the tips prepared by DC methods, which produce sharp tips. A two-step method involving a combination of AC and DC methods can be used to get cusp-shaped tips, which are sharp and stubby. They are sometimes dipped in hydrogen fluoride to remove tungsten oxide prior to washing in distilled water, particularly for application in air. Atomic resolution can be reproducibly obtained from electrochemically etched tips by repeated tunneling or scanning or crashing the tip against the sample, or by further processing either by heating with or without electric fields, bombarding them with electrons or ions, or by operating the tip in the field emission mode. Tungsten tips are generally used for ultrahigh vacuum (UHV) applications because of the ease with which they can be etched to a radius of less than 1000 Å and cleaned in UHV by annealing or field evaporation. Platinum and platinum-based alloys (Pt–Rh, Pt–Ir) are often used for STM imaging in air because of their oxidation resistance. Due to the inherent chemical inhomogeneity, tips of alloys have a greater tendency to form microasperities than single element tips after etching. In spite of the arbitrariness in the formation of microasperities, several methods have been developed empirically to process the tips which produce atomic resolution routinely.\(^{13–21}\)

The sample preparation for UHV involves application of standard techniques in surface analysis, namely heating, sputtering, cleaning and so forth. In air, the samples can be studied as received, but the surface is often contaminated with such substances as carbon and water vapor and one has to be careful in interpreting the results.

### 4.5 Vibration and Acoustic Isolation

The exponential dependence of tunnel current on distance makes vibration isolation extremely critical in STM design and installation.\(^{43–46}\) Since vertical resolution depends on the mechanical stability of the tunnel junction, the noise must be well below 0.01 nm for attaining atomic resolution. There are two main approaches adopted for vibration isolation of STM. The first is spring suspension with eddy current damping and the second is a stack of metal plates separated by rubber spacers. The first one is very effective for resonance frequencies close to 1 Hz. The second one has the advantage of simplicity and ease of operation. While most of the commercial STMs come with adequate vibration isolation, care must be exercised to make sure that STM is not installed in noisy areas.
4.6 Scanning Tunneling Spectroscopy Experimentation

The instrumentation for tunneling spectroscopy is simple and requires few additional digital-to-analog (D/A) and analog-to-digital (A/D) channels and software for the data acquisition system in addition to sample and hold circuit to the feedback loop. A/D channels are required to measure $dI/dV$ and D/A channels for programming the tunneling voltage and tip position. The tip position can be programmed by adding a summing input to $z$-piezo high voltage amplifier. The timing sequence for obtaining the basic tunneling spectrum involves moving the tip to the desired location while the feedback is on, and recording the $I-V$ curve by ramping the voltage. For a better signal-to-noise ratio, the bias voltage can be modulated for the lock-in detection. The dynamic range of the measurement can be increased by freezing the feedback and moving the probe toward the sample during the voltage sweep. Basic concepts underlying the other methods have already been discussed in section 3.5. Unlike STM imaging, where sharp tips are desirable, STS requires blunt tips as STS from sharp tips often exhibit non-reproducible tunneling spectra. Blunt tips are usually produced by positioning the tip at 100 Å from a metal substrate and drawing a few µA of field emission current at a few hundred volts. This procedure not only cleans the tip by local heating, but also melts it, leading to blunting. Such tips tend to have a reproducible density of states.

5 ILLUSTRATIVE APPLICATIONS

5.1 Structure of Crystal Surfaces [1]

Because of the inherent ability of STM to obtain real-space, atomic resolution images of smooth surfaces, it is widely used in the field of surface science for the investigation of single crystal surfaces. If a surface characterized by Miller indices $(hkl)$ does not relax or reorient after formation, then the resultant surface is called ideal. Surfaces of low index planes such as $(110)$ body-centered cubic or $(111)$ face-centered cubic are densely packed. These planes are generally atomically smooth and referred to as “singular” planes because they exhibit local minima in free energy plots. A surface whose orientation differs only slightly from the singular planes is termed vicinal. Such a surface is characterized by flat terraces separated by widely spaced atomic steps or ledges. The steps are straight or jagged (kinked) depending on their vicinality. The surfaces have a tendency to reconstruct and the effect is more pronounced in semiconductors due to the presence of dangling bonds. The various reconstructions are denoted by $(m \times n)$, where $m \times n$ refers to the two-dimensional Miller indices needed to
describe the surface unit cell in terms of bulk lattice vectors. At elevated temperatures or in the presence of gases, a phenomenon known as faceting occurs, where the original surface of uniform step density decomposes into hill-and-valley structures consisting of two types of plane. One of the planes has low Miller indices and the other is more complex, involving crowded steps of several atomic layers with an orientation necessary to keep the average surface orientation parallel to that of the original surface. STM and STS have been extensively used for the direct observation of a variety of surfaces at the atomic scale. A wealth of information is available in a great many papers and several books. It will not be possible to review all these results to any degree. In the following section a brief discussion of the general approach adopted for application will be described to highlight the experimental achievements and future potential of the techniques.

5.1.1 Metals, Semiconductors, Superconductors and Oxides

5.1.1.1 Metals The simplest materials that can be investigated by STM are metals. Metals require relatively low bias (a few millivolts) because there are states at Fermi levels into or from which the electrons can tunnel. Since metals are good conductors, applied bias voltage across the barrier can be used directly as an energy parameter in spectroscopy. Because wavefunctions at Fermi energy are generally S-like, the charge density clearly follows the atomic corrugation and therefore the images can be directly related to the surface topography. Atomic resolution is generally difficult on closely packed surfaces, due to lack of surface states. The observed STM images generally show atomic steps and reconstructions. As an example, Au (110) has been found to consist of channels in [110] direction with lengths of several hundred angstroms. The channels could be interpreted as (1 × 2), (1 × 3) and sometimes (1 × 4) reconstructions. Figure 7 shows the STM image of a (1 × 2) reconstructed domain on a Au (110) surface in 0.1 M HClO₄ where potential induced reversible transition between nonreconstructed (1 × 1) and a reconstructed surface exhibiting (1 × 2) and (1 × 3) symmetries occur. Similar observations have been made in UHV conditions. It was found that kink sites on the Au (110) (2 × 1) surface are highly mobile, which appears to be important for nucleation and growth of this phase.

5.1.1.2 Semiconductors STM images of reconstructed semiconductors have been described. These images are often beautiful, with clearly resolved atomic features. However, there are several difficulties in their imaging; for instance, because of low conductivity there is a considerable voltage drop over the sample.

Figure 7 (a) STM image of a (1 × 2) reconstructed domain on a Au (110) surface in 0.1 M HClO₄ at an electrochemical potential of −0.3 V. (b) STM image of a (1 × 3) reconstructed domain. [Reproduced with permission from X. Gao, A. Hamelin, M.J. Weaver.]
The topographic maxima are usually associated with surface dangling bonds. According to their energy, certain images may be seen at some particular bias voltage. It is therefore necessary to perform voltage dependent STM/STS studies. A clean Si (111) has been known to reconstruct into a (7 × 7) structure upon heating typically above 1000 °C in UHV conditions (<10⁻¹⁰ mbar) and subsequent cooling to ambient temperatures. STM images of Si (111) (7 × 7) surface reveal 12 adatoms per unit cell, as shown in Figure 8. The dangling bonds on the adatoms are partially filled and therefore contribute to both empty and filled states. Si (111) (7 × 7) is a surface for which STM images directly provide geometric information about the positions of the surface atoms.

5.1.1.3 Superconductors

STM/STS has been used for the investigation of the local atomic and electronic structures of high-temperature superconductors (HTSC). Among the different HTSC which are oxides, the Bi- and Ti-based oxides have been widely investigated because clean surfaces are easily obtained by cleaving the samples. STM images of Bi₂Sr₂CaCu₂O₈⁺ₓ reveal the atomic lattice and a superimposed incommensurate superstructure consisting of a sinusoidal modulation with a periodicity of 9–10 unit cells along the [010] direction and a periodicity of 4.5–5 unit cells. Local tunneling spectroscopy measurements on Bi-based compounds have revealed a lack of density of states at Fermi level, indicating that the surface of the BiO layer is not metallic. The other types of HTSC have also been investigated, namely YBa₂Cu₃O₇₋ₓ and Pb₂Sr₂(Y, Ca)Cu₃O₈₋ₓ, although with some difficulty because they do not cleave easily. Figure 9 shows a typical top view of two edge dislocations on a single crystal of Pb₂Sr₂(Y, Ca)Cu₃O₈₋ₓ. STM has also been widely used for surface morphology of sputter and laser deposited YBa₂Cu₃O₇₋ₓ thin films (Figure 10).

5.1.1.4 Oxides

In STM, there is an obvious requirement that the sample should have sufficient conductivity so that trouble-free imaging is possible. It turns out that metallic oxides have the required conductivity and they have been successfully investigated using STM. The oxides that have been imaged with atomic resolution include the HTSC discussed in the preceding section, ReO₃, WO₃, sodium tungsten bronzes NaₓWO₃, together with oxide bronzes such as blue bronzes MoₓMoO₃ and Fe₃O₄. For these materials, STM imaging is possible at either positive or negative sample bias. Stoichiometric transition metal oxides such as TiO₂, WO₃, SrTiO₃, and BaTiO₃ are intrinsically poor conductors; however, annealing in UHV or a partial pressure of hydrogen results in bulk oxygen loss, rendering them extrinsic.

Figure 8 (a) STM topograph of the unoccupied states of the clean (7 × 7) surface (top), and the atom-resolved tunneling spectra (below). Curve A gives the spectrum over a rest atom site, curve B gives the spectrum over a corner adatom site, and curve C gives the spectrum over a center adatom site. Negative energies indicate occupied states, while positive energies indicate empty states. (b) STM topograph of the unoccupied states (top) and atom-resolved tunneling spectra (below) of an NH₃ exposed surface. Curve A gives the spectrum over a reacted rest atom site, curve B (dashed line) gives the spectrum over a reacted corner adatom, while curve B (solid line) and C give the spectra over an unreacted corner and a center adatom, respectively. Figure 10
Highly mobile and also diffuse across the terraces of Cu adatoms evaporating from surface step edges are originating from dissociative chemisorption, can diffuse at room temperature, the highly mobile oxygen adatoms, studied for a variety of metal substrates. For instance, of the experiment. Adsorption of oxygen has been and surface mobility of the adsorbate at the temperature strongly on the applied bias voltage, electronic structure which often lead to the formation of ordered layers. Interactions between adsorbed atoms and molecules, at determining the nature of the binding sites and on the phenomenon of adsorption has been directed in numerous reactions at solid surfaces. Research work

Adsorption of other species such as carbon, sulphur, carbon monoxide and halogens on metals has also been investigated. Investigation of the initial stages of oxidation of semiconductor surfaces is important and has been investigated using STM. These studies have shown that defect sites on the clean Si (111) (7 × 7) surfaces, such as vacancies or (7 × 7) domain boundaries, act as nucleation centers for the oxidation process. The straight atomic steps were found to be relatively insensitive to oxygen exposure. Atomic hydrogen adsorption on a Si (111) (7 × 7) surface has been investigated with a view to understanding the formation and disruption of the silicon–hydrogen bond, due to its importance in many technologically valuable processes. The direct bonding of hydrogen atoms to existing surface dangling bonds is observed at low coverage. Increasing hydrogen exposure results in the removal of the uppermost silicon adatom layer, accompanied by binding of hydrogen atoms to the dangling bonds created. The STM images reveal (1 × 1) structures in the background of (7 × 7) unit cells.

(n-type) semiconductors. It is possible to image these surfaces by tunneling into empty states at negative sample bias. Other alternatives to circumvent the conductivity problem involve the deposition of a thin conducting layer of metal such as Au, carrying out of experiments at elevated temperatures, or growing an epitaxial layer on the metal substrates. A typical STM image of an oxide, like metals and semiconductors, will exhibit an ordered array of maxima and minima in addition to steps, dislocations and other such defects. In metals, the maxima invariably correspond to atomic position; in semiconductors, they may correspond to atomic position or may involve electronic structure. In oxides, the interpretation of STM images is not always unambiguous. A major issue, therefore, is to establish a correspondence between maxima in gray scale images and atomic positions within the unit cell. 

5.1.2 Adsorption, Surface Diffusion and Surface Chemistry

5.1.2.1 Adsorption Adsorption is a necessary step in numerous reactions at solid surfaces. Research work on the phenomenon of adsorption has been directed at determining the nature of the binding sites and interactions between adsorbed atoms and molecules, which often lead to the formation of ordered layers. STM images of adsorbate-covered metal surfaces depend strongly on the applied bias voltage, electronic structure and surface mobility of the adsorbate at the temperature of the experiment. Adsorption of oxygen has been studied for a variety of metal substrates. For instance, at room temperature, the highly mobile oxygen adatoms, originating from dissociative chemisorption, can diffuse on terraces of the unconstructed Cu (110) surface. Cu adatoms evaporating from surface step edges are highly mobile and also diffuse across the terraces of the substrate surface. This results in nucleation of the (2 × 1) phase, consisting of single strings of copper atoms glued together by oxygen atoms. Similar anisotropic island formation has been reported for other planes and different adsorbate substrate combination. The periodicities of superstructures are found to depend on the oxygen coverage and the substrate temperature. Adsorption of other species such as carbon, sulphur, carbon monoxide and halogens on metals has also been investigated. Investigation of the initial stages of oxidation of semiconductor surfaces is important and has been investigated using STM. These studies have shown that defect sites on the clean Si (111) (7 × 7) surfaces, such as vacancies or (7 × 7) domain boundaries, act as nucleation centers for the oxidation process. The straight atomic steps were found to be relatively insensitive to oxygen exposure. Atomic hydrogen adsorption on a Si (111) (7 × 7) surface has been investigated with a view to understanding the formation and disruption of the silicon–hydrogen bond, due to its importance in many technologically valuable processes. The direct bonding of hydrogen atoms to existing surface dangling bonds is observed at low coverage. Increasing hydrogen exposure results in the removal of the uppermost silicon adatom layer, accompanied by binding of hydrogen atoms to the dangling bonds created. The STM images reveal (1 × 1) structures in the background of (7 × 7) unit cells. 

5.1.2.2 Surface Diffusion Surface diffusion of adatoms is central to the understanding of a variety of phenomena, such as adsorption, chemical reactions and surface phase transitions. Direct atomic scale observation of surface diffusion and the determination of the diffusion coefficient, activation energies and atomic migration frequency is possible using STM. Further analysis of the images yields quantitative information about diffusion anisotropy and its correlation to atomic sites. Diffusion coefficients as low as $10^{-17}$ cm$^2$ s$^{-1}$ ($10^{-21}$ m$^2$ s$^{-1}$) can, in principle, be measured using STM. Before the advent of STM, such low diffusion constants were measured using FIM, and valuable information is available on diffusion of metal atoms on metal surfaces. However, the techniques for diffusion of atoms on semiconductor surfaces did not exist prior to STM invention. Although some experimental difficulties still prevent accurate measurement of the absolute value of the diffusion coefficient, investigations have been carried on the atomic-scale dynamics of adsorbed atoms, giving a glimpse of the future potential of this technique. Recent real-time observation of the dynamics of single Pb atoms on Si (111) suggest that single Pb atoms are mobile within each half (7 × 7) unit cell. Individual jumps of single atoms between different half-cells have been resolved, with a measured activation energy of 0.64 ± 0.07 eV. In
contrast, the motion of Pb atoms on Ge (111) C (2 × 8) structures takes place between well-defined equilibrium positions. STM observations for Si and Ge adatoms on top of Si (100) (2 × 1) indicate a strong anisotropy in the surface diffusion process due to the dimer-type (2 × 1) reconstruction. Diffusion is typically a thousand times faster along the surface dimer rows than perpendicular to them.17

5.1.2.3 Surface Chemistry Understanding of a catalyst’s structures as well as the structure of adsorbed molecules under catalytic reaction conditions is important for elucidating how a reaction progresses on the atomic scale.88,89,90 STM investigation of a Pt (111) crystal surface in the presence of a hydrogen–propylene mixture (10:1) at 1 atmosphere and room temperature reveals featureless terraces separated by straight mono-atomic height steps, even though the surface is catalytically active and propylene is hydrogenated to propane during STM imaging. The most significant result of the in situ STM images was that the underlying platinum atoms were not significantly reconstructed by the adsorbed species. Controlled experiments performed by annealing the sample to temperatures > 770 K in propylene to form carbon clusters result in substantial reconstruction, and STM was sensitive enough to observe it. The steps were no longer straight but exhibited a propensity for kinks or protrusions in the steps that are pinned on the top of some clusters. These results indicate that STM is especially suitable for imaging defects at high pressures and elevated temperatures and is capable of detecting stationary species and adsorbate-induced surface restructuring as it occurs during chemisorption or a catalytic reaction. STM, however, cannot at present image surface species that are mostly small chemisorbed organic molecules at 300 K or above. STM can be combined with surface-specific vibrational spectroscopy such as sum-frequency generation (SFG), which can operate under dynamic high-pressure reaction conditions to get additional information about the molecular structure of the adsorbrates and reaction intermediates.91

5.1.3 Thin Film Morphology, Nucleation, Growth, etc. A study of nucleation and growth of thin films has been an active area of research for the last several decades because its outcome has a direct bearing on a variety of processes of technological importance. Typical nucleation and growth experiments involve characterization of films obtained under a variety of controlled deposition conditions. The experiments using STM during the last 10 years have provided quantitative information on island distribution within each layer, their dependence on external parameters, temperature and deposition flux and their strong dependence on interlayer transport. The importance of STM lies in its ability to actually observe islands, thin shapes, size, coverage and spatial distribution on atomic length scales.92 Traditionally, three different growth mechanisms have been identified based on thermodynamic consideration: Frank–Van der Merwe for monolayer growth, Volmer–Webber for initial film nucleation by 3-D crystallite formation and Stranski–Krastanov for formation of an initial uniform layer followed by 3-D crystallite growth.93 Recently, it has been realized that these thermodynamic models need to be modified to account for kinetic limitations. The solid films grown under far from equilibrium conditions are consistently predicted to have self-affine surfaces and are therefore candidates for a recently developed dynamical scaling approach. The experimental determination of growth exponents has been an area of intense activity during this decade and STM, because of its ability to measure roughness with unprecedented resolution, has contributed enormously to this field.94 The field of nucleation and growth investigation using STM has advanced considerably, and several exhaustive review articles and monographs are available on this topic.95,96,97 The atomic scale mechanisms involved in crystal growth strongly depend on crystal growth conditions and crystallographic orientation of the substrate. Even if the direct observation of atomic scale growth processes may not be possible in every such case, the morphology of layers formed during the growth can provide information about growth processes like surface diffusion, island formation and growth at step edges98 (Figure 11).

STM has also been used for the investigation of films grown under most real-life environments. The growth of diamond by chemical vapor deposition (CVD) is one such example. In recent years, the subject of diamond films prepared by CVD has emerged as a technologically useful and scientifically interesting field of research.99,100

The diamond films are usually prepared by the hot-filament method, the microwave plasma CVD method, or by a combination of both. Several investigations have been reported on the application of STM for

Figure 11 STM image (300 nm × 150 nm) of a high cover age (>5ML) Cu film after room temperature deposition. Multilayered islands of characteristic pyramidal shape are formed, whose edges are oriented along the closed-path directions of the substrate. [Reproduced with permission from G. Pötschke, J. Schröder, C. Günther, R.O. Hwang, R.J. Behm, Surf. Sci., 251/252, 592 (1991).]
nucleation-growth investigation of diamond films.\(^{(97–99)}\) In one of the recent works,\(^{(100)}\) the diamond films grown by the conventional hot filament CVD method (HF–CVD) using a hydrogen–methane (100:1) gas mixture (gas flow of 100 sccm), with a chamber pressure of 30 torr at substrate temperature \(T_c\) ca. 850° C to 900° C for a duration of 3 to 4 h were investigated using STM. Because of the high band gap (5.4 eV) of diamond, the films had to be doped by irradiating them with boron ions of 500–800 keV with doses up to \(10^{14}\) ions cm\(^{-2}\), and annealed at high temperature for successful STM imaging. The SEM images of these films showed diamond crystallites with predominantly (100) facets. The STM images showed a large number of pyramidal nanofacets exhibiting layered structure (100) symmetry commensurate with the underlying facet. The smallest terrace top was typically ca. 50 Å and showed no evidence of dislocations. The quantitative analysis of results indicates that the transport processes such as surface diffusion are more dominant than evaporation, condensation processes in the growth of (100) diamond, leading to layer-by-layer growth (Figure 12).

5.1.4 Surface Electronic Structure

The origin of electronic structure effects in STM imaging has been discussed in section 3.5. The electronic structure effects have been investigated for a variety of metals and semiconductor surfaces.\(^{(13–27)}\) Only two of the many celebrated applications will be considered here to illustrate the type of electronic information available from STM/STS results. It is well known that cleaving of Si (111) surface in UHV results in a Si (111) (2 \(\times\) 1) structure, in contrast to (7 \(\times\) 7) structures after annealing cycles at >800 °C. This is a metastable surface and its STM image is dominated by electronic effects.\(^{(101–103)}\) The voltagedependent images in Figure 13 show that the maximum in the image taken at +1 V appears as a minimum at −1 V because, as seen in the center of the cross-hairs in the two images indicating shift in topographic maxima by half a unit cell in the [011] direction. The results are consistent with \(\pi\)-bonded chain model.\(^{(104)}\) The two adatoms in the unit cell of this model are nonequivalent due to the underlying symmetry of the lattice and also possibly due to buckling of the chain. Tunneling at positive sample bias then accesses the empty states while at negative bias it probes the filled states.

One of the striking examples of electronic structure studies using STM is the adsorption of NH\(_3\) on the...
Si (111) (7 × 7) surface. Figure 8 shows STM images of clean (a) and NH₃ exposed surfaces. (b) NH₃ is known to dissociate on the Si (111) (7 × 7) surface, producing Si=H and Si–NH₂ groups. The reacted atoms appear dark because of the saturation of their dangling bonds by the chemical reaction process, leading to decrease in the LDOS near \( E_F \). It turns out that the products of surface reaction can also be imaged at negative sample bias, probing the occupied electronic states. These images are very rich in electronic information. Firstly, STM images of clean Si (111) (7 × 7) clearly show two nonequivalent types of surface Si adatoms, called “corner adatoms” and “center adatoms”. It can be seen that the majority of unreacted sites are “corner adatoms”, while the “center adatoms” exhibit a significantly higher degree of local reactivity. The influence of the reaction process on the local electronic structure can be directly studied by comparing local \( (dI/dV)/I/V \) – V characteristics, where \( I \) is tunnel current and \( V \) is the bias voltage. It must be noted that such detailed information would not be available from conventional surface analytical techniques averaged over large surface areas. Even in less ideal environments, namely those for the investigation of oxides, diamond films and so forth, the special resolution of STM is far better than the conventional techniques.²⁰⁶–²⁰⁸

5.1.5 Organic Molecules, Biological Molecules and Electrochemistry

5.1.5.1 Organic Molecules STM has been extensively used for imaging molecules in organic conducting salts or organic molecules adsorbed on various conducting substrates.²⁰⁹ Although STM images of organic adsorbed molecules are spectacular and clearly resolve complex multilayer structural details at the molecular level, the structural characterization of the organic adsorbate has not yet met with the same success as metals or semiconductors. In most cases, the molecular order at the liquid–solid interface is found in the vicinity of the substrate surface. The topmost layers are usually etched away by the tip, which makes it difficult to characterize their surface properties away from the interface. In almost all cases, one is imaging the interface and therefore the observed ordered layers are sensitive to substrate topography. On the atomically flat surface of graphite or specially prepared gold or silver films, organic molecules tend to form a lamellar structure. The mismatch between the molecular shape and surface topography also influences the ordered layer formation. One solution would be to develop more sensitive instruments which would operate at low current (picoamperes) and probably high bias (>10 V). Under this condition STM works in field emission mode.

Organic conducting salts are prepared as high-quality single crystals that are stable in air, and the crystals are characterized by well-defined flat surfaces. The molecular arrangements of these surfaces have been resolved using STM.²¹⁰ Although there are difficulties in the interpretation of images as they appear to depend on imaging conditions, there is a strong indication that tip–sample force interaction exists, leading to the removal of the surface layers, the migration of molecular defects and changes in the positions of the topmost molecular group. Some of the organic molecular systems that have been extensively investigated are: liquid crystals, alkanes and alkane-derived molecules, Langmuir–Blodgett (LB) films, polymers and fullerene films.

5.1.5.2 Biological Molecules The greatest incentive to use STM for the investigation of biological molecules is its ability to operate in an atmospheric and fluid environment and observe the in vivo dynamics of processes as they occur in real time. In addition, STM techniques are less destructive than most of the conventional electron microscopy techniques, which involve bombardment with high-energy electrons. However, there are major challenges involved in the successful application of STM to biological molecules, such as specimen preparation, location of features of interest, and the understanding of image contrast for thick micromolecules. In spite of these problems, imaging of biological specimens is one of the most rapidly growing applications of STM and has been extensively used for the investigation of nucleic acids, proteins and membranes.²¹⁷

5.1.5.3 Electrochemistry The techniques for the investigation of solid–vacuum or solid–gas interfaces at atomic level have advanced considerably, although corresponding techniques for liquid–solid interfaces are still scarce. With the advent of STM, it has been possible for the first time to investigate the microstructure of a solid–liquid interface and its relation to other properties. The two STM-based techniques that operate in electrolyte solutions are: scanning electrochemical microscopy (SECM)²¹⁰ and scanning ion conductance microscopy (SICM).²¹¹ The SECM uses the faradic current for stabilization of the tip–sample distance. The resulting image combines topographic information and the electrical and chemical properties of the sample. In SICM, a micropipet filled with electrolytes scans the sample. The conductance between micropipet and sample depends on the cross-section of the ion path and thus on the distance between micropipet and sample. The resolution depends on the micropipet opening but can be as small as 1000 Å.²¹¹ As an example of an application of STM in electrochemistry, it has been directly shown for a Au (110) surface in 0.1 M HClO₄ solution that a
reversible potential-induced transition between a nonreconstructed (1 × 1) and a reconstructed surface exhibiting (1 × 2) symmetry occurs. The results obtained for a Au (110) surface structure are largely consistent with the missing-row model.

5.1.6 Atom Manipulation and Nanolithography

The basic geometry of STM, a sharp tip held in close proximity to the sample surface with nanometer precision, lends itself as a powerful tool for nanofabrication, i.e. fabrication at the nanometer level by controlling the interaction necessary for imaging, manipulation and modification by adjusting the tip–sample distance or by changing the strength of interaction, that is by changing the bias voltage across the junction. A tantalizing glimpse of atom-by-atom manipulation by STM was demonstrated by Eigler and Schweizer in which xenon atoms were moved into the desired location and the pattern thus formed was subsequently imaged at liquid helium temperatures in UHV conditions. In another application, Xe atoms were reversibly transferred between tip and the sample using high-voltage pulses of opposite polarity at low temperatures. The scratching and indentation by the STM tip has also been used for mechanical modification of surfaces. The localized electron transport provides an extremely effective focusing of electrons both by tunneling and field emission modes. This, along with the inherent electric field in the tunnel junction, renders STM a versatile tool for electron lithography. A variety of electron beam resists, such as hydrocarbons, metal halides, poly(methyl methacrylate) (PMMA), and LB films have been exposed by STM operated in field emission mode (bias voltage higher than work function). Line widths below 100 nm have been routinely achieved. The other methods based on chemical surface modifications using low-energy electrons offered by STM include: local oxidation passivated semiconductor surfaces, electron enhanced etching, electron stimulated desorption, decomposition of organometallic gases and electrochemical etching and decomposition.

6 COMPARISON WITH OTHER METHODS

6.1 Scanning Tunneling Microscopy Compared with High-resolution Electron Microscopies

In the context of atomic resolution capability, there are very few techniques, namely STEM, TEM, and FIM which perform as well as STM, but they do so under special circumstances. For instance, STEM and TEM use high-energy electron beams, require very thin film samples, underlying periodic structures and large mass contrast such as heavy atoms on carbon film. FIM is usable only for refractory metals which can withstand the high electric fields required for imaging. In addition, only edge atoms on flat parts of a few hundred angstroms size are visible. In STM, the energy of the tunneling electrons is very low, typically a few meV to a few volts and electric fields three to four orders of magnitude less than FIM. Unlike REM, which has near atomic resolution only in the vertical direction, STM has very high vertical and lateral resolution, yielding a true 3-D topography of planar surfaces on the atomic scale. An inherent limitation of STM is that it always operates at high resolution and, therefore, works better for atomically flat surfaces. Such surfaces, however, can be easily prepared by standard techniques such as annealing, sputtering and cleaving in UHV.

The most important characteristic of STM that distinguishes it from other techniques is its somewhat surprising ability to operate in a variety of environments, such as air, reactive gases, liquids, electrolytes, greases and biological fluids. In addition, imaging with a lateral resolution of nanometers is important in the context of potential applications of STM in technologically important areas such as thin film device fabrication, preparation and characterization of industrially important surfaces, and surface roughness measurement.

6.2 Scanning Tunneling Spectroscopy Compared with Other Electron Spectroscopies

The surface spectroscopic techniques that can be compared with STS are: ETS, IETS, UPS and IPS. In contrast to conventional ETS and IETS, STS does not require high-quality oriented films. Also, there is no electric breakdown problem because a vacuum or air forms the barrier instead of an oxide, leading to a larger accessible energy range (typically an energy window of $E_F \pm 3$ eV). In addition, it can be performed locally at a preselected position under well-defined conditions and can be used in combination with other surface sensitive techniques, and provides spectroscopic images of electron states. In comparison with UPS and IPS, which probe a depth comparable to the escape depth of electrons (5 nm), STS is more surface sensitive because of its strong dependence on wave function overlap, which takes place only at a separation of a few angstroms. Moreover, it is able to detect both occupied and unoccupied states by simply reversing the tunnel bias.

7 SCANNING PROBE MICROSCOPY: RECENT TRENDS AND FUTURE PROSPECTS

The advent of STM has revolutionized our ability to see objects never seen before, and with minimum or no
sample preparation. The STM originally gained attention as a simple instrument for imaging atoms. Just a few years after its invention, it has established itself in surface science as an indispensable tool and is now being used in combination with other surface science techniques such as Auger electron spectroscopy (AES) and LEED. In the early years, most STMs were built in-house. Now they are available commercially; however, the trend is still to build them for very specific applications. From its modest beginnings, STM has instigated the growth of a family of instruments leading to a totally new means of investigation, SPM. In its most basic form, SPM senses some interaction between the proximal probe and the sample as a function of the distance between the object and the probe. If the interaction probe is either repulsive or attractive van der Waals force then the investigation is by atomic force microscopy (AFM). If frictional force is measured, then it is called lateral force microscopy. If electric force or magnetic force is monitored, then it is called electric force microscopy or magnetic force microscopy. If the spatial variation of the evanescent field is probed by a sharp scanning fiber optical probe, the technique is called scanning near field optical microscopy. The derivatives of each of the above methods have led to an arsenal of different techniques. In just a decade or so of its existence, SPM has been transformed from a laboratory curiosity into one of the most powerful and versatile techniques in the optics, semiconductor, and computer industries.

1 Introduction

Photoelectron spectroscopy (PES) is widely used for the chemical analysis of solid surfaces. When ultraviolet (UV) light or X-rays are incident upon a solid surface, electrons are emitted via the photoelectric effect. PES involves measurements of the kinetic energy distribution of the emitted electrons. If a monochromatic light source is employed, then the kinetic energy distribution reflects the
filled density-of-states (DOS) of the material. The DOS contains information related to the electronic structure and chemical composition of the near-surface region and to the bonding of adsorbates. Because the mean free path for electrons traveling in solids is fairly short, of the order of atomic dimensions, a PES spectrum reflects the DOS of the outermost few atomic layers of the solid.

When PES is used to measure the core-level, or inner-shell, electrons using a conventional X-ray tube, it is known as XPS or electron spectroscopy for chemical analysis (ESCA). The latter term has been coined to reflect the fact that chemical oxidation states are routinely obtained with this technique. The X-rays commonly employed for XPS are the Mg Kα (1253.6 eV) or the Al Kα (1486.6 eV) lines. For general information on XPS, see the article X-ray Photoelectron Spectroscopy in Analysis of Surfaces in this encyclopedia.

More recently, synchrotron radiation light sources have been developed to provide high-resolution, high-intensity and tunable sources of electromagnetic radiation. PES performed with synchrotron radiation has significant advantages over conventional XPS. One of the advantages is the ability to use smaller photon energies (longer wavelengths). These energies correspond to the soft X-ray and vacuum ultraviolet (VUV) regions of the electromagnetic spectrum. Hence, SXPS is often used to denote XPS performed with synchrotron radiation. In addition, the tunability of synchrotron radiation allows for types of measurements not possible with a fixed energy X-ray source.

Some of the major advantages in employing synchrotron radiation for XPS are:

- The photon energy is tunable over a wide range (typically 10–1000 eV for SXPS). This allows the excitation energy to be adjusted in order to enhance a particular spectral feature, as well as for additional types of spectroscopy in which the photon energy is continuously varied.
- The spectral resolution is greatly enhanced over that of a conventional X-ray source. This allows for the identification and quantification of spectral features not otherwise discernible.
- The brightness of the beam can be much greater than that of conventional X-ray sources, thereby allowing for the detection of very small photoelectron signals. For example, the photoelectrons emitted from a microscopic region of a surface can be detected, thereby enabling chemically sensitive microscopy. The brightness available with synchrotron radiation has been further increased with the recent advent of third-generation light sources, which provide much more intense radiation.
- Synchrotron radiation is naturally polarized, which allows for the dipole selection rules to be exploited for spectroscopy. For example, the angular dependence of the photoelectron signal on the incident beam direction can be used to determine the orientation of molecules adsorbed onto a surface.

Since much of the theory and analysis of SXPS data is the same as for XPS, except that the resolving power of SXPS is much greater, this chapter emphasizes those aspects of SXPS that are peculiar to synchrotron radiation. SXPS has been applied to a wide variety of materials, including metals, semiconductors, adsorbates on surfaces and nanoparticles. Note that many of the examples given in this chapter are from the author’s own laboratory. These particular examples were chosen because of their usefulness in illustrating the technique, and are not intended to be representative of the variety of materials that can be studied with SXPS.

2 PHOTOELECTRON SPECTROSCOPY

In PES, a photon is absorbed by direct excitation of a bound electron to a final state above the vacuum level, $E_{\text{vac}}$. This process is illustrated in Figure 1, which shows a photon of fixed energy, $h\nu$, being absorbed by the system, and the subsequent emission of an electron from a bound atomic core level. If the electron is excited above $E_{\text{vac}}$, it is emitted from the surface where it can be measured by an electron spectrometer.

\[ h\nu = \text{Photon energy} \]
\[ E_{\text{vac}} \]
\[ E_{\text{Fermi}} \]
\[ \phi = \text{Work function} \]
\[ E_{\text{bind}} \]
\[ \text{Valence band} \]

Figure 1 Schematic diagram illustrating the photoemission process. An electron bound with energy $E_{\text{bind}}$ absorbs a photon of energy $h\nu$. The electron is emitted from the surface with kinetic energy $E_{\text{kin}}$. 

Atomic core level

Synchrotron radiation is naturally polarized, which allows for the dipole selection rules to be exploited for spectroscopy. For example, the angular dependence of the photoelectron signal on the incident beam direction can be used to determine the orientation of molecules adsorbed onto a surface.
The binding energy ($E_{\text{bind}}$) is the minimum energy required to remove an electron from a bound state. In other words, $E_{\text{bind}}$ is the energy needed to excite the electron to the first empty state of the solid, which is just above the Fermi level. In order to escape into vacuum, the electron also needs sufficient energy to overcome the surface work function, $\phi$. Thus, as illustrated in Figure 1 and shown in Equation (1), conservation of energy implies that

$$h\nu = E_{\text{bind}} + E_{\text{kin}} + \phi \quad (1)$$

The outcome of the photoelectric effect is to translate the filled DOS, represented by the valence band and core levels, to energies above the vacuum level. Figure 2 illustrates how the photoemission process translates the filled DOS into a photoelectron spectrum by translating the entire distribution of filled states to positions above the vacuum level. If the probability for photoemission, i.e. the cross-section, were constant, then the measured photoelectron spectrum would be an exact representation of the filled DOS. Note that a real photoelectron spectrum would reside on top of a background of secondary electrons, which is not shown in Figure 2.

Peaks are seen in PES spectra that correspond to the valence band and to each bound core-level electron in the material. The intensity of each core-level peak is proportional to the abundance of the corresponding element in the near-surface region, while the precise binding energy of each peak is a function of the chemical oxidation state and the local environment of the emitting atoms. The Perkin–Elmer Handbook of X-ray Photoelectron Spectroscopy contains sample spectra, collected with traditional XPS, of each element and a table of binding energies for certain compounds, and is useful as a reference.\(^4\)

Note that core levels are often split into two resolvable components by the spin–orbit interactions. This spin–orbit splitting is an atomic effect, and is changed little by the presence of the surface or by the formation of chemical bonds. The result is that a doublet in a PES spectrum often represents a single atom in a single chemical environment. A spin–orbit doublet is described by two parameters: the spin–orbit splitting and the branching ratio. The spin–orbit splitting is the difference in binding energy between the two components. The branching ratio is the relative areas of the two components. To first approximation, the branching ratio will be that determined by statistics. For example, a p-level contains four electrons in the $p_{3/2}$ orbital and two electrons in the $p_{1/2}$ orbital. Thus, the $p_{3/2}$ and $p_{1/2}$ components have a statistical branching ratio of 2:1. Often, however, final state effects (discussed below) will slightly alter the measured branching ratio away from the statistical value.

The photoemission process involves the excitation of an electron from its bound initial state to an unbound final state. The matrix element for the transition determines the photoemission cross-section. This cross-section depends on the photon energy employed. There are tables, which are useful for quantitative analysis, that list the atomic cross-section as a function of the photon energy.\(^5\) The presence of the surface has only a minor effect on the overall cross-section. Note, however, that in performing quantitative analysis one must also take into account how the sensitivity of the electron spectrometer varies as a function of the measured kinetic energy, as well as the electron escape depth, which is discussed below.

The transition probability, $w_{fi}$, can be calculated from Fermi’s Golden Rule\(^7,8\) as shown in Equation (2)

$$w_{fi} = \frac{2\pi}{\hbar} |\langle \psi_f | \psi_i \rangle|^2 \delta(E_f - E_i - \hbar\nu) \quad (2)$$

where $\psi_i$ and $\psi_f$ are the initial and final state wave functions. The simplest approximation in applying this rule is to assume one-electron wave functions for the initial and final states, and that the final state has a free electron with energy $E_{\text{kin}}$. Much more sophisticated

---

**Figure 2** Schematic diagram illustrating how photoemission translates the filled DOS into a photoelectron spectrum. The length of the vertical arrows represents the photon energy.
SURFACES

Theoretical approaches have also been applied to this problem. The fundamental shape of a single core-level photoelectron component is that of a Lorentzian that has been broadened by a Gaussian. The Lorentzian component is the natural shape of an atomic state, whose width derives from the Heisenberg uncertainty principle. The longer the lifetime of the excited state produced by photoemission, the more certain is the energy of that state. Thus, the Lorentzian width is often called the lifetime broadening. The Gaussian contribution to the width of a core-level feature comes from the instrumental resolution and from inhomogeneous broadening in the material. Either or both of these sources of broadening can be significant and often dominate an experimental spectrum. Instrumental broadening will affect each component in a spectrum in a similar manner, whereas inhomogeneous broadening could be different for different components. Inhomogeneous broadening includes phonon broadening and broadening due to atoms occupying a range of local environments.

3 SURFACE SENSITIVITY

Electrons are extremely useful as surface probes because the distances that they travel within a solid are very short. This insures that any electrons created deep within a sample do not escape into vacuum. Techniques that rely on measurements of low-energy electrons emitted from solid surfaces therefore provide information from just the outermost few atomic layers. Because of this inherent surface sensitivity, the various electron spectroscopies are probably the most useful and popular techniques in surface science. The reason that electrons interact strongly with solid materials is that they readily scatter from the various components of a solid. When electrons scatter inelastically, they lose energy to the solid so that the kinetic energy is reduced and the electrons no longer contribute to a spectroscopic feature. The most important inelastic scattering mechanism is the excitation of plasmons. A plasmon is a collective excitation of the electrons in a material. Electrons can also scatter elastically, which may cause them to change direction so that they are no longer emitted. Elastic scattering can also, however, increase the photoelectron yield due to diffraction, which is discussed below.

The inelastic mean free path (IMFP) characterizes the average distance that an electron travels through a solid before it is annihilated by inelastic scattering. Early efforts were made to derive a “Universal Curve” for the IMFP as a function of the electron kinetic energy. It was later realized, however, that the IMFP varies from material to material. Figure 3 shows the IMFP plotted as a function of the electron kinetic energy for a few selected materials. In general, the IMFP has a minimum that corresponds roughly to the plasmon energy. When the kinetic energy is too small, electrons can no longer excite plasmons. As the kinetic energy increases above the plasmon energy, the probability for excitation decreases. Thus, the electrons with the smallest mean free path for most materials are those with approximately 30 to 100 eV of kinetic energy. The specific location of the minimum and the detailed shape of the IMFP function differ from one material to the next. SXPS will generally be, however, much more surface sensitive than traditional XPS owing to the lower kinetic energy of the photoelectrons that are typically measured.

There have been various attempts at quantifying the penetration depth of electrons in order to use XPS for analytical purposes. The IMFP accounts for inelastic scattering, but electrons can also scatter elastically. Thus, the electron escape depth has been defined, which is the quantity that specifies how far an electron has traveled within a sample and includes losses by all possible mechanisms. For quantitative analysis, however, what is actually needed is the mean distance below the surface from which the photoelectrons have originated. This depends on the angle of emission, roughly as the cosine of the angle, since electrons emitted at more grazing angles spend more time below the surface. The mean escape depth (MED) takes into account the emission angle in order to define the photoelectron yield in terms of the depth of origin, rather than the distance traveled through the solid. Although the values will differ, the
general shape of the MED curve is similar to that of the IMFP shown in Figure 3. In general, values of the escape depth for 10–200 eV electrons, which are the important electrons for SXPS, range from 4 to 10 Å, which is of the order of the interlayer spacings of a solid.

Electron attenuation is most often modeled by assuming that the yield of electrons originating from a particular depth within the sample decreases exponentially with increasing depth, as shown in Equation (3)

\[
\text{Number of electrons} = \exp \left( \frac{-d}{\Delta} \right)
\]

where \( \Delta \) is the MED for electrons in the material, and \( d \) is the distance below the surface from which the electron originated. This exponential attenuation model is often used for quantitative analysis, although it has some limitations. A measurement can be difficult to analyze, for example, if the MED changes as electrons travel from one region of an inhomogeneous sample to another.

A consideration of electron attenuation allows a determination of the depth distribution of elements within a sample by changing either the emission angle or the electron kinetic energy in order to vary \( \Delta \). Varying the emission angle, which is also routinely employed in conventional XPS measurements, changes the path length through which the photoelectrons travel within the solid. Thus, at more grazing emission angles, the surface sensitivity is increased. Then, a comparison of spectra obtained at a grazing angle to spectra collected at normal emission provides a measure of the depth distribution. At a synchrotron light source, the tunability of the radiation can be exploited to change the escape depth. For example, in order to maximize the surface sensitivity of the measurement, the photon energy can be selected to be approximately 20–50 eV above the binding energy of the desired core level. Or, in order to compare spectra that sampled different depths below the surface, spectra could be collected employing a surface-sensitive photon energy and one that produced electron kinetic energies that were not as surface sensitive. For example, a common method for obtaining a bulk-sensitive spectrum is to use kinetic energies well below the plasmon energy. In addition, if levels from different elements are being compared, the photon energies employed for the collection of each spectrum could be selected such that all of the electron kinetic energies are nearly equal. In this way, each spectrum would probe the same depth into the sample.

4 ENERGY DISTRIBUTION CURVES

The standard SXPS spectrum is collected as an energy distribution curve (EDC). For an EDC, the photon energy is fixed and the kinetic energy distribution of the emitted photoelectrons is measured. This is the same manner in which traditional XPS spectra are collected. EDC spectra can be used to probe either the valence band or core-level states.

Note that EDC spectra are often displayed with respect to the binding energy, rather than the electron kinetic energy, in order to reflect the properties of the material, rather than those of the spectrometer. Because spectroscopists are accustomed to viewing spectra plotted in terms of increasing kinetic energy, however, the convention has arisen to plot PES spectra in reverse, i.e. from high binding energy on the left to low binding energy on the right.

For valence band spectroscopy, photon energies in the range of 20 to 50 eV are usually employed, as this represents the region of maximum cross-section for valence band photoemission. Traditional ultraviolet photoelectron spectroscopy (UPS) employing an He discharge lamp is limited to the He I and He II lines at 21.2 and 40.8 eV. An advantage to the use of synchrotron radiation for valence band PES is that a wide range of photon energies is available. As the photon energy changes, the relative contributions to the spectra of various atomic and molecular orbitals change, which is a great aid in delineating the spectroscopy of a system.

Synchrotron radiation is also particularly useful for angle-resolved photoelectron spectroscopy (ARPES), also called angle-resolved ultraviolet photoelectron spectroscopy (ARUPS). In this technique, measurements are made of the valence band photoelectrons emitted into a small angle as a function of the electron emission angle or photon energy. This allows for the simultaneous determination of the kinetic energy and momentum of the photoelectrons with respect to the two-dimensional surface Brillouin zone. From this information, the bulk and surface electronic band structure of a single crystal material can be experimentally determined via the procedure called “band mapping”.

SXPS usually refers to core-level spectroscopy. Each core-level EDC contains peaks that correspond to emission from a particular inner-shell atomic level of an element in the near-surface region of the material. The intensity of each core-level peak is related to the abundance of that element in the near-surface region. The exact position of the peak, i.e. the binding energy, is related to the local chemical environment of the emitting atoms.

A single core-level peak often contains multiple components, in which the different components arise from atoms in inequivalent chemical configurations. Sometimes the individual components will be clearly resolved from each other. Often, however, a particular peak will be composed of a sum of unresolved components. These components
are then delineated from each other by a numerical curve-fitting procedure, as described below. In either case, the positions of the various core-level components are used to identify the chemical species present on the surface, and the relative intensities are then used to determine the distributions of the various chemical states.

5 CURVE FITTING

In order to interpret high-resolution SXPS data, it is often necessary to deconvolve the spectra into their individual core-level components. This allows for a determination of how many separate states exist for each element in the surface region, the binding energy associated with each of these states, and their relative abundance. Care must be taken in fitting, however, to make sure that the result is physically reasonable. It is easy to get a good fit by introducing extra components into an analysis. Usually, the least number of components that are required to provide a good fit should be used.

Before a spectrum can be fitted, the secondary electron background signal must be removed from the raw data. The shape of the secondary electron distribution depends on the details of the electronic structure of the material, as it results from photoelectrons that have lost energy by inelastic scattering from various excitations in the solid. This produces a cascade of secondary electrons whose intensity increases towards lower kinetic energies. The background underneath any particular photoelectron feature consists of secondary electrons that were produced both extrinsically and intrinsically. The extrinsic secondary electrons originated as higher energy photoelectrons, i.e. from the valence band and from lower-lying core levels. The intrinsic secondary electrons originate from the photoelectron peak itself. The process of background subtraction is illustrated in Figure 4, which shows SXPS data collected from Si(100) reacted with chlorine gas.\(^{(15)}\)

The background due to the extrinsic secondary electrons can be determined experimentally. An experimental background spectrum is collected by measuring the electron yield over the same kinetic energy region as was used for the SXPS data, but employing a lower photon energy. In this manner, the direct photoemission peaks are moved to kinetic energies below the region over which the spectrum is collected. This gives a good experimental measurement of the shape of the background due to higher energy photoelectrons. As an example, Figure 4(a) shows a raw photoelectron spectrum, collected with \(h\nu = 130\) eV, along with a measured background collected with \(h\nu = 120\) eV. Figure 4(b) shows the spectrum after the experimental background was subtracted. Note that the experimental background was approximated by a smooth polynomial prior to subtraction so as not to introduce additional noise into the data.

After removal of the experimental background, there is still a background arising from the intrinsic secondary electrons. This is seen in the data of Figure 4(b), where a clear background signal is visible at kinetic energies below the peaks, while there is no background above the peaks. This intrinsic background signal must be removed numerically. The most common method used to numerically model the secondary electron background in SXPS is that devised by Shirley.\(^{(16)}\) Note that often a Shirley-type background is calculated directly from the raw data, i.e. removal of an experimental background is not essential. In the Shirley method, the region on both sides of the peak is considered separately from the region underneath the peak. Away from the peak, the background signal can be fitted to a polynomial. Underneath the peak, the yield of intrinsic secondary electrons is considered to be proportional to the integral of the peak. The implicit assumption here is that the loss of photoelectrons is constant throughout the spectrum. Figure 4(b) shows data along with a Shirley-type background calculated from the data, and Figure 4(c) shows the data after the background has been removed.

After background removal, the data are composed of a sum of components that correspond to the different chemical states present in the surface region. A single component, however, is often composed of a spin–orbit doublet. In Figure 4(c), for example, it might initially appear that there are three distinct states of Si. The spin–orbit splitting can be numerically removed, however, which simplifies the analysis. In order to remove the spin–orbit splitting, the background must first be

![Figure 4 SXPS spectra collected from Cl\(_2\) gas adsorbed on Si(100), illustrating background subtraction and spin–orbit deconvolution.](image)
subtracted, and the spin–orbit parameters must be known and assumed to be the same for each component. Figure 4(d) shows the result of spin–orbit deconvolution of the data in Figure 4(c). After removal of the spin–orbit splitting, it is seen that there are actually only two major components: one that represents Si in the substrate and the other that represents surface Si atoms that are attached to Cl.

After background subtraction, the data are numerically fitted to a sum of Gaussian-broadened Lorentzian lineshapes using a least-squares procedure. The fit can be performed either with or without first removing the spin–orbit splitting.

**Figure 4 (Continued)**

### 6 CHEMICAL SHIFTS

The binding energy of a core-level component depends on the bonding configuration and local environment of the emitting atom. The nominal energy of the core-level state is determined by the atomic orbital, but the binding energy is modified in forming a molecule or solid. In addition, the exact binding energy associated with a particular arrangement within a solid depends on many other factors. The amount that the binding energy changes when an atom goes from one chemical state or environment to another is referred to as the chemical shift.

When the atoms at the outermost surface differ in binding energy from the bulk, i.e. substrate, atoms, the difference in binding energy is called a surface core-level shift (SCLS). A surface shift could arise simply because an atom is located at the surface, where its chemical environment differs from that of the bulk, or due to the chemical bonding of an adsorbate to the surface. Note that often only the chemical shifts between the substrate and surface atoms are reported, rather than the absolute binding energies.

Photoemission occurs by excitation of a ground state electron from its initial state to an excited final state. The final state produced by the photoemission process lacks one electron as compared to the initial state. Thus, the binding energy that is measured is actually the difference between the neutral ground state system and the ionized final state. Note that there is no direct way in which to experimentally measure the binding energy of an electron as it exists in the neutral ground state.

Chemical shifts result from a combination of initial state and final state effects, as changes to the chemical environment of an atom alter both the ground state and the excited state energies. Initial state effects result from phenomena such as charge transfer, Madelung energy and rehybridization. The energy of the final state depends on the interaction of the photoelectron with the ionized system. Thus, final state effects contribute to chemical shifts via alterations of the screening that photoelectrons experience at the surface.

To first approximation, changes in the initial state configuration can be considered to be the major contributor to chemical shifts. The largest factor that contributes to determining the binding energy of the initial state is the chemical oxidation state of the atom. As the oxidation state increases, the density of valence electrons that surround an atom decreases due to charge transfer away from the atom. The remaining core electrons then become more tightly bound to the nucleus since fewer valence electrons are there to screen the interaction. Thus, the more positive the oxidation state, the higher the binding energy will be. Note that in many XPS and
SXPS studies, it is only the oxidation states of the surface atoms that are of interest.

There has been theoretical work employing a Born–Haber cycle in order to calculate core-level shifts and to elucidate the relative importance of initial and final state effects.\(^{(19-21)}\) Since the charge seen by the photoelectron is a combination of the nuclear charge plus the core hole, the final state produced by photoemission from an atom of atomic number \(Z\) can be approximated by a neutral atom of atomic number \(Z + 1\). Then, for example, a chemical shift due to an adsorbate can be related to the difference in bond energy of that adsorbate to elements \(Z\) and \(Z + 1\).

The theory is, however, not sufficiently developed that it can be used to reliably calculate binding energies. Thus, for most applications, binding energies are determined empirically regardless of the nature of the chemical shifts. In general, the amount that initial or final state effects contribute to a chemical shift is unimportant in performing spectroscopy for chemical analysis.

Note that in most SXPS studies, the photoelectric cross-section of a particular component is assumed to be unchanged when the binding energy of that component is altered by chemical bonding or other effects. There have been some reports, however, in which the cross-section for photoemission has been shown to be affected by changes in the oxidation state due to chemical bonding.\(^{(22)}\) These effects are likely due to changes in the final state DOS that occurs with increasing oxidation state. An increase in the final state DOS will increase the probability for photoemission, as can be seen from Equation (2). Shape resonances, which are enhancements of the final state DOS, are well known from X-ray absorption studies, and are often larger for atoms in higher oxidation states. Thus, it is not surprising that photoemission cross-sections are sometimes affected by the chemical state of the emitting atom. Also, such a nonconstant final state DOS can act to slightly alter the spin–orbit branching ratio measured in an EDC spectrum. Although these effects are usually not too severe, they can be avoided by using constant final state (CFS) photoemission, as described below.

### 6.1 Clean Surfaces

The outermost atoms on a clean surface are chemically and structurally different from the bulk atoms of a material. Thus, there are often clearly resolvable SCLS components in spectra collected from clean surfaces.\(^{(23)}\) In a bulk-terminated or relaxed surface, the SCLS component would have an intensity corresponding to one monolayer of atoms. In a reconstructed surface, however, there can be a number of SCLS components, each corresponding to atoms in different structural positions.

Figure 5 shows an SXPS spectrum collected from clean W(110), which has a bulk-terminated surface structure.\(^{(24)}\)

The inset shows the entire W \(4f\) spectrum, which encompasses both the \(4f_{7/2}\) and \(4f_{5/2}\) levels. (Reproduced from Citrin et al., *Phys. Rev. Lett.*, 63, 1976 (1989) by permission of the American Physical Society.)

The in-set shows the entire W \(4f\) spectrum, which includes the \(4f_{7/2}\) and \(4f_{5/2}\) spin–orbit-split levels, which are completely resolved from each other. It is seen that each level is composed of two features, the one at lower binding energy (rightmost) being the bulk component and the higher binding energy feature (leftmost) being the SCLS component. The main figure shows a blow-up of the \(4f_{7/2}\) level along with a numerical fit. The SCLS is nearly as intense as the bulk component in this spectrum, which attests to the surface sensitivity of this measurement. Because the surface atoms are in a different environment from the bulk atoms, their binding energy is lower by 0.32 eV, even though there is no change in the formal oxidation state.

An example for a reconstructed semiconductor surface is given in Figure 6, which shows an SXPS spectrum collected from clean Si(100)-2×1 along with a numerical fit.\(^{(17)}\) In this spectrum, there is a bulk component and two SCLS components. One SCLS is shifted to higher binding energy and the other to lower binding energy. The nature of these shifts can be understood in simple
soft x-ray photoelectron spectroscopy in analysis of surfaces

Figure 6 Si 2p SXPS spectrum collected from clean Si(100)-2×1 with a photon energy of 130 eV. The data, following background subtraction, are shown as dots. The solid line shows the result of a numerical fit to the data, while the dashed lines show the individual components of the fit. Each individual chemical component is split into the Si 2p3/2 and 2p1/2 contributions by the spin−orbit interaction. The inset shows an illustration of an asymmetric surface dimer that is believed to terminate this surface.

terms by consideration of the geometry at the Si(100)-2×1 surface. The Si surface atoms form asymmetric dimers, as shown in the inset, in which the outer dimer atom has a filled orbital and is nearly sp3 hybridized, while the other atom has an empty orbital and is nearly sp2 hybridized. Because the outer atom has more electron density associated with it, the binding energy of the core electrons is decreased. Hence, it is associated with the low binding energy component. The inner dimer atom has a lower electron density surrounding it, and hence it is associated with the high binding energy SCLS component.

6.2 Adsorption

When adsorbates attach to surface atoms, chemical shifts are often observed in the SXPS spectra. The usual cause for this is the transfer of charge to (from) electronegative (electropositive) adsorbates. In some cases, the effects of adsorption are to simply remove the SCLS components associated with the clean surface. The identification, concentration and bonding configuration of surface adsorbates is obtained from analysis of SXPS spectra.

As an example, Figure 7 shows an SXPS spectrum that was collected from a silicon surface following reaction with XeF2 (a source of atomic fluorine). The photon energy was chosen to be 130 eV so that the electron kinetic energy would be approximately 25 eV, i.e. near the minimum escape depth. The raw data, following background subtraction, are shown along with a numerical fit to the data. There are four resolvable spin−orbit doublets in the spectrum, which correspond to the substrate Si and to surface Si atoms that are attached to one, two and three fluorine atoms, i.e. Si, SiF, SiF2 and SiF3. It is seen that the bonding of each fluorine atom causes an approximately 1 eV shift to the binding energy. In this case, the main contribution to the chemical shift is the change in oxidation state. As additional fluorine atoms attach to each Si atom, the oxidation state is increased and charge is removed from the Si atom. The more charge that is removed, the more the binding energy increases. The resolution and surface sensitivity afforded by synchrotron radiation were necessary in order to resolve the SiFx features. Results such as these are extremely useful in determining the pathways of surface chemical reactions.

The example shown in Figure 8 shows how SXPS can be used to determine the binding site on a binary material. Figure 8(b) and (d) show In and As spectra collected from the clean InAs(001)-c(8×2)/(4×2) surface, in which the clean surface SCLS components S1 and S2 can be seen. In Figure 8(a) and (c) the spectra collected following iodine adsorption are shown. It can be clearly seen that iodine attaches solely to the surface In atoms.

6.3 Quantitative Analysis

In order to calculate the coverage of an adsorbate from the ratio of two SXPS core-level peaks, the photoemission cross-section, the electron escape depths and the incident photon flux must all be known. The cross-section can be found from a table. The escape depth can be obtained
Figure 8 SXPS spectra collected from clean InAs(001) and from InAs(001) following reaction with I$_2$. (b) and (d) show In 4d and As 3d spectra, respectively, from the clean surface, while (a) and (c) show In 4d and As 3d spectra, respectively, collected from the surface saturated by iodine. The data, following background subtraction, are shown as dots. The solid line shows the result of a numerical fit to the data, while the dotted lines show the individual components of the fit.

7 OTHER MODES OF SOFT X-RAY PHOTOELECTRON SPECTROSCOPY

Because of the tunability of synchrotron radiation, there are other ways in which SXPS and related data can be obtained. The following methods can only be performed with synchrotron radiation, as it is necessary to continuously vary the photon energy.

7.1 Constant Final State Photoemission

Photoelectron spectra can be collected by setting the electron energy analyzer to measure electrons at a fixed kinetic energy and then varying the photon energy. When the photon energy is such that Equation (1) holds for a particular filled state, a peak will appear in the spectrum. In this manner, the final state that is involved in the transition is fixed over the entire spectrum, while the initial state is varied. Thus, this method of collecting spectra is called CFS spectroscopy. The analysis of CFS data is somewhat simpler than EDC, as both the initial and final states vary across an EDC spectrum. Another advantage to the CFS technique is that cross-section changes due to final-state shape resonances do not influence the lineshapes within a spectrum. In addition, the electron escape depth remains constant across the spectrum. CFS photoemission has not been commonly employed despite these advantages, however, as most researchers are more familiar with EDC spectra. Also, it takes longer to collect a CFS spectrum, as the monochromator needs to be adjusted continuously, and many software packages do not have this as an option.

The same experimental conditions used for CFS data collection are also used for X-ray absorption spectroscopy. In X-ray absorption, the probability for the absorption of photons is measured as the photon energy is varied. For surface work, the yield of secondary electrons is monitored, which is assumed to be proportional to the absorption probability. If all of the emitted secondary electrons are collected, such a spectrum is labeled as total electron yield (TEY). Often, however, only a portion of the secondary electron distribution is monitored, i.e. the...
particular electron yield (PEY) is collected. A PEY spectrum might be collected, for example, by monitoring the Auger electrons emitted from a particular atom or the yield at a surface sensitive kinetic energy, such as 25 eV. A PEY spectrum can be collected using the same instrumentation employed for SXPS.

X-ray absorption spectroscopy is commonly used to measure the electronic and geometric structures of surfaces by varying the photon energy and collecting a TEY or PEY spectrum. When the energy corresponding to a transition from a filled core level to the Fermi energy is reached, the probability for absorption greatly increases and a core-level edge is observed in the spectrum. When probing the region close to an edge, the technique is referred to as near edge X-ray absorption fine structure (NEXAFS) or X-ray absorption near edge spectroscopy (XANES). NEXAFS provides a good measure of the unoccupied DOS, and is particularly useful for studies of molecular adsorbates. When probing the absorption of a surface over a wide range of photon energies above a core-level edge, the technique is called surface extended X-ray absorption fine structure (SEXAFS). SEXAFS, which is the surface analog to the popular EXAFS technique, provides a measure of the nearest neighbor bond lengths and coordination for atoms at the surface.

### 7.2 Constant Initial State Photoemission

In constant initial state (CIS) spectroscopy, the photon energy and electron kinetic energy are ramped together in such a way that  

$$E_{\text{kin}} = h\nu - \phi = E_{\text{bind}}$$

is kept constant. In this way, the intensity of a single photoelectron feature is measured as the final state is varied. For valence band spectroscopy, this is useful for mapping out the empty DOS of the conduction band in order to compare with electronic structure calculations. By combining EDC and CIS spectra, a complete picture of the occupied and unoccupied DOS can be obtained. For core-level spectra, CIS spectroscopy is one method that can be used for mapping out changes to the photoelectron yield due to diffraction, as discussed below.

### 7.3 Resonant Photoemission

Valence band EDC spectra contain contributions from the various atomic and molecular orbitals that comprise the electronic structure of a material. As the photon energy is changed, the relative contributions of each of these levels to the spectra change. Monitoring these changes is one manner in which the details of the electronic structure of the surface region can be elucidated.

A more dramatic enhancement of certain valence band features occurs, however, when the photon energy employed also corresponds to the excitation energy of an inner-shell electron, i.e. at a core-level edge. Such an enhancement of a particular valence band feature is known as resonant photoemission. When the photon energy is just above a core-level edge, the incident beam induces direct photoemission from the valence band while at the same time it creates core holes. The core holes will be filled by an Auger process, in which one valence electron falls down to fill the hole, while a second valence electron is emitted from the surface in order to satisfy conservation of energy. Resonant photoemission occurs because the Auger electron that is released will have the same kinetic energy as the valence band photoelectrons affiliated with that element. This is because the valence electrons that have the highest probability for making these transitions are the ones associated with the atom whose inner-shell orbital is being filled. Thus, element-specific valence band features are enhanced at energies corresponding to the core-level edges of that element.

Resonant photoemission has been applied to the determination of the electronic structure of a number of materials, such as metals, oxides, superconductors, and other materials that display correlations in the behavior of their electrons.

### 8 OTHER INFORMATION OBTAINED FROM SOFT X-RAY PHOTOELECTRON SPECTROSCOPY

In addition to concentrations and chemical shifts, there is other information that can be obtained by analysis of SXPS data.

#### 8.1 Band Bending/Fermi Level Pinning

For a semiconductor or insulating sample, the Fermi level can be positioned anywhere within the band gap, i.e. between the valence band maximum (VBM) and the conduction band minimum (CBM). The location of the Fermi level within the band gap is known as the pinning position, and the precise value is of critical importance in electronic devices as it determines the height of the Schottky barrier at an interface. Because of the importance of Fermi level pinning, there have been many studies in which changes in the pinning position have been monitored as a function of metal overlayer growth.

The Fermi level is pinned by the existence of partially filled states in the band gap, such as surface electronic states, defect states, or states induced by an adsorbate or metal overlayer. Note that some materials, such as clean III–V semiconductor (110) surfaces, are unpinned, i.e. they have no states in the gap. For an unpinned
surface, the Fermi level is located near the CBM for n-type material and at the VBM for p-type. When an adsorbate attaches to the surface of one of these unpinned materials, states form that act to pin the Fermi level. Thus, these surfaces are ideal for studies of Fermi level pinning mechanisms.

When the Fermi level is pinned at the surface, all of the electronic energy levels bend as they move deeper into the sample. This is illustrated in Figure 9. The slope of this band bending is usually shallow enough so that SXPS measures only the photoelectrons that originate from the outermost surface, i.e. the region in which the Fermi level is pinned. Note that if the band bending were steep with respect to the electron escape depth, the SXPS peaks would be broadened. The measured kinetic energies of all of the photoelectrons are affected by the pinning position. When the pinning position is altered, the bands bend and the kinetic energies of the photoelectron peaks move up or down accordingly. The movement of a sharp SXPS peak is therefore used to monitor the position of the Fermi level due to the surface photovoltage (SPV) effect.

8.2 Work Function Measurements

Electron spectrometers measure kinetic energy with respect to their own vacuum level. This is illustrated in Figure 10, which shows a sample with a slightly larger work function than that of the analyzer. The thick vertical arrow indicates the lowest kinetic energy electron that can be emitted from the sample, and how it would appear to have a finite kinetic energy when measured by the analyzer. This is essentially another way of stating that there is an electric field between the sample and analyzer due to the work function difference, and this field accelerates the electrons into the detector. Thus, a measurement of the position of the low energy cutoff of the secondary electron distribution provides a measure of the surface work function. Note that it is common to apply a small (~5 to 10 V) bias to the sample so that the cutoff of secondary electrons is always well above the analyzer vacuum level. The position of this secondary electron cutoff shifts if the sample work function is changed, for example by the adsorption of alkali atoms. Monitoring shifts to the work function does not provide an absolute measure of the surface work function, but it can be calibrated by comparison to a cutoff measured from a known surface. Changes to the work function that occur as a surface is altered are important in understanding many kinds of surface phenomena.

8.3 Polarization Effects

The light from a synchrotron radiation source is linearly polarized in a direction perpendicular to the beam. A particular photoelectron transition can be either allowed or forbidden, depending on the projection of the matrix element for the transition, i.e. Equation (2), onto the polarization vector. Thus, for example, the relative angle between the polarization direction and the direction of a chemical bond on a surface can affect the intensity of a given photoelectron feature. PES can then be used to determine the orientation of adsorbates on surfaces by monitoring a valence band signal as a function of angle. Note that this cannot be used for core-level studies since diffraction effects (see below) will dominate the angular distributions. However, the polarization of synchrotron radiation is often exploited in NEXAFS for determining the bond angle of a molecular adsorbate.
The polarization directions are usually defined as s-polarized and p-polarized. In the s-polarized configuration, the polarization vector of the light is parallel to the sample, while for p-polarization it is perpendicular to the sample. Thus, for s-polarization the beam is incident normal to the surface, while it is incident at a near-grazing angle for p-polarization. Note that it is possible to get a completely s-polarized configuration, but it is not possible to be 100% p-polarized since the incident beam cannot be aligned perfectly along the plane of the surface and still induce photoelectron emission.

9 NOVEL APPLICATIONS OF SOFT X-RAY PHOTOELECTRON SPECTROSCOPY

In addition to collecting standard SXPS spectra for chemical analysis, there are many other unique uses of this technique. In addition, the advent of insertion devices and third-generation synchrotron light sources, which are described below, has furthered the development of some of these novel applications by providing more intense radiation sources. Some of the latest developments are described here.

9.1 High-resolution Photoelectron Spectroscopy

The high brightness available from third-generation light sources has improved the performance of extremely high-resolution SXPS. The high brightness is necessary so that when the spectral width of a beam is made extremely narrow, there is still a sufficient photon flux remaining to be able to produce a measurable signal. In addition, the sample is usually cooled to reduce the phonon broadening in order to obtain ultrahigh-resolution SXPS spectra from solids.

For example, ultrahigh-resolution SXPS spectra collected from the Si(111)-7×7 surface enabled the delineation of at least six SCLS components, instead of the usual two components measured under more conventional conditions. An example is given in Figure 11, which shows a comparison of spectra collected at liquid nitrogen and room temperatures. In these spectra, the Gaussian broadening was reduced to the point that the spectra actually appear by eye to have a Lorentzian shape. Ultrahigh-resolution SXPS has also been applied to measurements of the electronic structure of quasicrystals. In this work, the Fermi edge was measured as a function of surface temperature using a 5-meV resolution. This was necessary in order to be able to compare the results with theoretical predictions, as the edge is extremely sharp.

Figure 11 Ultrahigh-resolution SXPS spectra collected at (a) 100 K and (b) 300 K from Si(111)-7×7 with a photon energy of 140 eV, shown along with a numerical fit to the data. (Reproduced from Le Lay et al., Phys. Rev. B, 50, 14 277 (1994) by permission of the American Physical Society.)

9.2 Soft X-ray Photoelectron Spectroscopy Microscopy

One of the more recent advances in SXPS is the development of photoelectron microscopy. SXPS microscopy allows for the collection of chemically resolved images. For example, the spatial variations of the photoelectron yield of each element in a material can be independently collected or an element- or oxidation-state-specific image can be obtained for systems with a resolvable core-level shift. This technique has many technological and environmental applications. For example, the chemical makeup of micromechanical and microelectronic devices can be viewed directly on the scale of the device dimensions.
There are two modes in which spatially resolved SXPS is performed. In “spectromicroscopy”, electrostatic lenses are employed to image the spatial distribution of the emitted photoelectrons. In “microspectroscopy”, the incident X-ray beam is focused onto a small spot and an image is acquired by moving the sample. High brightness is an integral part of the development of SXPS microscopy, as it is needed in order to provide sufficient photoelectron signal from a microscopic region. Thus, most of this work requires an insertion device beamline. The limit to the spatial resolution is currently of the order of 1000 ˚A, but is expected to reach 100 ˚A in the near future.

Figure 12 shows an example of SXPS microscopy images collected from a naturally occurring ilmenite sample. Figure 12(a) shows spectra that were collected from two different regions of the sample surface. One region shows an enhancement of Fe, while the other shows an enhancement of Ti. Figure 12(b) and (c) shows micrographs collected by monitoring either Fe or Ti photoelectrons. These images clearly show the Fe- and Ti-rich domains on the surface.

9.3 Photoelectron Diffraction/Holography

X-ray photoelectron diffraction (XPD) is routinely used to obtain the atomic structure of the surface region of a crystalline sample. When electrons of a well-defined energy are created at a particular atomic site, such as in SXPS, the emitted electrons will interact with other atoms in the crystal structure prior to leaving the surface. The largest effect is “forward scattering”, in which the intensity of an electron wave emitted from one atom is enhanced when it passes through another atom. Thus, the angular distribution of the emitted electron intensity provides a “map” of the surface crystal structure. Forward scattering dominates at high photon energies. At lower photon energies, however, there is a more complex diffraction behavior in which the intensity modulations do not necessarily lie along the atomic bond directions. This kind of multiple scattering in electron diffraction produces variations of the emitted electron intensity with respect to angle and energy. In order to determine a surface structure from such diffraction data, the measured angular and/or energy distributions of the photoelectrons are compared to a theoretical prediction for a given structure. The structure employed for the calculation is varied until the best fit to the data is found.

One of the advantages of using synchrotron radiation for XPD studies is that the photon energy, and not just the emission angle, can be adjusted. Another advantage is that the large photon flux allows for spectroscopy to be performed on a much quicker timescale. This is particularly important for photoelectron diffraction.

---

Figure 12 Scanning SXPS microscopy of a natural ilmenite sample. (a) SXPS spectra collected from two different regions, A and B, of the surface using a photon energy of 420 eV. (b) SXPS micrograph image acquired by monitoring the Fe 3p photoelectrons. (c) SXPS micrograph acquired by monitoring the Ti 3p photoelectrons. The regions used in (a) are indicated in (c). (Reproduced from Tonner et al., Surf. Interface Anal., 27, 247–258 (1999) by permission of John Wiley & Sons.)
as there are typically a large number of spectra that must be collected in order to properly determine a surface structure. As an example, Figure 13 shows angular distributions of the S 2p core level, each collected with a different photon energy from a clean PbS(001), i.e. galena, surface (B.P. Tonner, unpublished results). Each pattern is marked with the electron kinetic energy used for measurement.

In photoelectron holography, the diffraction pattern represented by the angular distribution of a particular photoelectron feature is measured and then directly converted into the real-space image of a surface structure. Thus, no model of the structure needs to be assumed, and there is no trial-and-error type of analysis in which artificial spectra are fabricated based on the model structures. This is similar to the manner in which X-ray diffraction is used to determine bulk crystal structures. Photoelectron holography is hampered by the difficulty in accurately measuring photoelectron angular distributions, however, as well as by the more complex scattering behavior of electrons as compared with X-rays. However, this technique is currently under development and much progress has been made in recent years.

### 9.4 Spin-polarized Photoelectron Spectroscopy

It is possible to measure not only the kinetic energy of a photoelectron, but also its spin. Spin-polarized studies have applications in the study of magnetic materials, and have led to an improved understanding of the origins of magnetic anisotropy. Spin-resolved valence and core-level spectroscopy have been performed on clean surfaces, adsorbate-covered and oxidized surfaces, and thin magnetic films. The inherent strength of spin-resolved measurements is the direct probing of the imbalance in the spin-up and spin-down population, which is the basis of the magnetic behavior. It has also been found that spin is important in describing photoemission from non-magnetic materials, in particular when using chiral experimental geometries, for example by employing polarized photon beams.

The spin of a photoelectron is measured with the use of a specialized spin-resolving detector, which is most often attached to the exit of the electron energy analyzer. The majority of today’s detectors are based on the spin-dependence in electron–solid scattering. The most commonly used is the Mott detector, which operates in the 10–100 keV range and uses Au as a target. The spin dependence in a Mott detector is produced by the spin–orbit part of the scattering potential, which is due to coupling of the electron spin and the angular momentum acquired in the scattering process. Since the spin–orbit part of the potential is proportional to the vector product of the spin and the angular momentum, the electrons scattered to the left acquire the opposite angular momentum from the ones scattered to the right, thereby producing different scattering probability for a given electron spin direction. The distribution of the spins is then measured with the use of two separate electron detectors and it is proportional to the asymmetry of the two intensities. Spin detectors are inherently inefficient (the figure of merit for Mott detectors is only $\sim 10^{-4}$) because of losses in the scattering process ($\sim 0.3$) and because there is only a limited spin asymmetry in the scattering. Thus, it is necessary to have a large incident photon flux in order to create a sufficient number of photoelectrons so that the signal can be detected. For this reason, spin-resolved PES is usually carried out at specialized insertion device beamlines, which are described below.

As an example, Figure 14 shows Fe 3p spectra collected from clean Fe(001) and after a small exposure to O$_2$. Figure 14(a) shows the spin-up photoelectrons and Figure 14(b) shows the spin-down photoelectrons both before and after oxidation. It is seen that oxygen adsorption produces a new chemical shift towards higher binding energy, and that the signal arising from the oxidized overlayer is not symmetric with respect to spin, indicating some net oxide spin polarization. Furthermore, this polarization is opposite to the polarization of the Fe metal indicating antiparallel coupling between the metal and oxide magnetic moments. This is effectively a spin-resolved version of SXPS, which illustrates the ability to separately identify the magnetic states of thin Fe oxide layers on top of Fe metal below.

Another method of probing magnetic properties is to use circularly polarized light to observe magnetic circular dichroism (MCD). In the MCD technique, photoelectron spectra are compared for light that is right-hand vs left-hand polarized. The difference in the spectra

---

**Figure 13** XPD angular distribution images of S 2p photoelectrons emitted from a clean PbS(001) surface. (Reproduced by permission of B.P. Tonner.)
reflects the spin character of the initial states. Circularly polarized light is required in order to perform MCD. Although synchrotron radiation is linearly polarized in the plane at the center of the beam, the light is elliptically polarized at the upper and lower portions of the beam. Thus, these portions of the beam are utilized for some MCD experiments. For more sophisticated measurements, however, specialized insertion devices are used to directly produce a high flux of circularly polarized light. Since the dichroism is based on the spin–orbit coupling in the photoemission process, the interpretation of MCD spectra is much less straightforward than the spin-resolved measurements. Nevertheless, MCD techniques allow for a much more efficient investigation of magnetic effects since they do not require a spin detector, and have thus complemented the spin-resolving measurements.

10 INSTRUMENTATION FOR SOFT X-RAY PHOTOELECTRON SPECTROSCOPY

Because of the need for intense, tunable radiation, SXPS is carried out at synchrotron light source facilities that employ an electron storage ring for the production of synchrotron radiation. In the USA, these include the National Synchrotron Light Source (NSLS) at Brookhaven National Laboratory, the Stanford Synchrotron Radiation Laboratory (SSRL), the Advanced Photon Source (APS) at Argonne National Laboratory, and the Advanced Light Source (ALS) at Lawrence Berkeley National Laboratory, among others. There are also other synchrotron light sources in operation, and new ones under construction, throughout the world. Most of these function as user facilities, so that any researcher with a good idea can get beamtime via the submission of a short proposal.

Aside from the storage ring, the instrumentation needed for SXPS spectroscopy consists of a monochromator and a spectrometer. The spectrometer is normally housed inside a UHV chamber. Like any surface science technique, SXPS must be carried out under UHV in order to maintain sample cleanliness. Synchrotron radiation storage rings must also be kept under UHV conditions in order to be able to maintain a stored electron beam for long periods of time. Thus, the entire storage ring, and each beamline attached to it, is essentially one huge interconnected vacuum system.

In the following sections, the three major components of an SXPS experiment are described. Note, however, that each beamline must also contain the instrumentation normally used to prepare surfaces for UHV studies, such as a sputter gun, sample manipulator, and low-energy electron diffraction (LEED) optics.

10.1 Storage Ring

The major piece of instrumentation for SXPS is the electron storage ring used to produce synchrotron radiation. An electron storage ring is a large donut-shaped vacuum chamber inside which electrons travel at relativistic velocities around a nearly circular path. The electrons are steered around the ring by a number of “bending magnets” and can be stored in a stable orbit for hours. When any charged particle is accelerated, there is a perturbation to the electric field that induces the emission of radiation. As each bending magnet alters the direction of the beam in a storage ring, synchrotron radiation is emitted primarily in the direction tangential to the electron path. At a typical storage ring that is being used as a light source, there are a large number of bending magnets, with each one attached to a “beamline”. The radiation is focused down the beamline by a combination
of grazing incidence X-ray mirrors so that it can be used for various experiments. Note that SXPS is only one of the many uses of synchrotron radiation.

The earliest, or first-generation, synchrotron radiation experiments were performed using accelerators that were built for high-energy physics experiments. These “parasitic” experiments provided the earliest SXPS results, but had as a disadvantage the fact that the available beamtime was dependent upon the experimental schedule of the particle physicists. The second-generation machines, such as the NSLS, were built specifically for the production of synchrotron radiation. These machines have become the cornerstones of synchrotron radiation research in providing stable, reliable beams for a large variety of experiments. The latest technology in synchrotron radiation light sources is represented by the third-generation machines, such as the ALS. The designs of these machines have been optimized for the use of insertion devices to increase the photon flux and brightness.

Insertion devices, such as undulators and wigglers, are placed directly in the path of the electrons traveling through the storage ring. Insertion devices use magnetic fields to rapidly accelerate the electron beam perpendicular to the propagation direction, which produces a strong enhancement of the photon yield at a particular energy by focusing all of the synchrotron energy into a narrow spectral region. Insertion devices can increase the brightness up to four orders of magnitudes above that available from a conventional bending magnet beamline.

10.2 Monochromator

A monochromator is used to select a single photon energy from the white light synchrotron radiation beam. The monochromators that are used for the soft X-ray region are based on the use of diffraction gratings of the grazing incidence reflection type. Grazing incidence is required so that the material of the grating does not absorb the X-ray beam. These gratings are of three general types, classified by the shape of the reflecting surface: (1) plane grating monochromator (PGM); (2) spherical grating monochromator (SGM); and (3) toroidal grating monochromator (TGM). Typical beamlines contain a selection of gratings, each optimized for a different spectral region. Before the beam enters the grating chamber, and also after it leaves, it is collimated by slits that allow only a narrow spectral region to pass. In more sophisticated beamlines, the slits move in a direction parallel to the beam as the photon energy is adjusted to insure that they are always located at the focal point of the grating. In addition, each beamline contains X-ray reflection mirrors used to steer and focus the beam onto the grating and then onto the sample.

10.3 Electron Energy Analyzer

Electron energy analyzers come in various types, but most use electrostatic deflection to measure electron kinetic energies. The most common is the hemispherical energy analyzer. These analyzers are constructed from concentric hemispherical sectors, and electrons travel between the two hemispheres. At the entrance to the analyzer, there is an electrostatic lens that is used to focus the electrons. At the exit of the analyzer, there is a channeltron or microchannelplate electron detector. The outer hemisphere is held at a more negative potential than the inner hemisphere, so that the electrons of the proper energy will follow the path between the hemispheres. Hemispherical analyzers can efficiently collect electrons emitted into a small angular region, and measure them with high spectral resolution. Cylindrical mirror analyzers (CMA) are also occasionally used for SXPS. In a CMA, electrostatic fields are used to focus electrons along cylindrical paths. CMAs collect a wider angular region than hemispherical analyzers, but are not as efficient and cannot achieve as high an energy resolution. There are also other designs for electrostatic analyzers, as well as time-of-flight analyzers.

Dresden, Dresden, Germany

1 Introduction

X-ray photoelectron spectroscopy (XPS) is an analytical technique that uses photoelectrons excited by X-ray radiation (usually Mg Kα or Al Kα) for the characterization of surfaces to a depth of 2–5 nm. Elemental identification and information on chemical bonding are derived from the measured electron energy and energy shifts, respectively. The use of ultrahigh vacuum (UHV) during analysis requires special sample handling. Depth profiling is possible using ion sputtering.

In contrast to the most popular surface analytical technique, Auger electron spectroscopy (AES), nonconducting material can be investigated, little material damage occurs, and the chemical shifts are easier to interpret. However, the lateral resolution of AES (typically 50 nm) is much greater than for XPS (50 μm for standard equipment, down to lower than 3 μm for dedicated instruments). The detection limit (of about 0.1 atom %) is not as low as for mass spectroscopic techniques, but the quantification from XPS peak area measurements is much better, even disclaiming standard sample measurements.

This article briefly discusses the principles of the technique, sample requirements, and the typical measuring strategy. Possible information sources (elements, chemical bonding, depth and lateral distributions) are described and their quantification principles are summarized. The main part deals with typical applications relating to several material classes (metals, semiconductors, insulators, polymers) to give a feeling for the effectiveness of the method over a wide range of research and technological problems. A comparison with similar techniques is given as a summary.

Technological developments in electronics, nanotechnology, polymers, biotechnology and medicine are all concerned with surface-related phenomena, suggesting sustained interest in XPS in the foreseeable future.

1 INTRODUCTION

XPS is an analytical technique which uses photoelectrons excited by X-ray radiation and released from the material into vacuum for the characterization of surfaces. The electrons in the (solid) sample are characterized by their binding energies (BEs) which depend on the element. Using only the elastically scattered electrons (electrons without energy losses) emitted from the sample, information on the composition of the sample may be derived from their energy spectrum. The energy spectrum is measured in an electron spectrometer and the measured kinetic energies (KEs) of the electrons are determined from their binding energy spectrum. The energy spectrum is measured in an electron spectrometer and the measured kinetic energies (KEs) of the electrons are determined from their binding energy spectrum. The energy spectrum is measured in an electron spectrometer and the measured kinetic energies (KEs) of the electrons are determined from their binding energy spectrum.

The surface sensitivity of the technique is determined by the relatively low escape depth (0.5–2 nm) of the
elastically scattered electrons. All elements of the periodic table can be detected by different characteristic BE peak positions (with the restriction that the light elements H and He may only be found with very low intensity in the valence band). The detection limits depend on the element and are typically in the range of 0.1–0.5 atom %. As the excitation does not use electrically charged particles, the method is dedicated to the measurement of electrically nonconducting materials. Radiation damage of the surface is small in comparison with electron beam excitation. Chemical information may be obtained by analyzing typical BE shifts of the photoelectron peaks, which depend on the chemical bonding of the elements under investigation.

However, because of the high surface sensitivity and to avoid energy losses of electrons in the analyzer region, the measurements require UHV conditions typically in the range of $10^{-9}$–$10^{-3}$ Pa. Sample information is often disturbed by surface contamination (mostly hydrocarbons or hydroxides) which requires special sample preparation or preconditioning. In multicomponent samples spectral overlap from several elements may occur, further complicated by X-ray excited Auger electron (XAES) lines.

The origin of the technique is connected with the discovery of the photoelectric effect by Hertz in 1887. In the early years of the twentieth century additional theoretical and experimental work was done. In 1914, Rutherford determined Equation (1),

$$ E_k = h\nu - E_b $$

which describes the measured electron energy $E_k$ as the difference of X-ray energy $h\nu$ and the electron BE $E_b$. Step by step the instrumentation was improved by various research groups; however, the modern XPS era is closely connected with the work of Siegbahn et al., dating from about 1954. They also introduced the acronym electron spectroscopy for chemical analysis (ESCA) which is often used. Industrial equipment became available in the 1970s and today XPS machines are among the most used surface analytical tools.

Valence band spectroscopy, which is often concerned only in context with ultraviolet (UV) excitation, should be regarded as an integral part of the XPS method. Although the interpretation of valence band spectra needs a lot of expertise, this technique is also briefly discussed.

The XPS method and its applications are described in considerable detail in monographs and review articles that summarize both the earlier and the more recent years of XPS development. Additionally the article by Turner (X-ray Photoelectron and Auger Electron Spectroscopy) in this Encyclopedia covers the whole field of XPS: physical principles, instrumentation and quantification. Consequently, this article covers the physics and theory only to the extent necessary to acknowledge the general application strategy and to interpret the examples discussed.

### 2 SAMPLE REQUIREMENTS, SAMPLE PREPARATION

The sample requirements are determined from the design of the particular electron spectrometer used and the physical principles of the technique itself. The minimum sample size is determined from the acceptance area of the analyzer, and the maximum sample size by the construction of the entry lock and the sample manipulating system (today up to 200 mm). Most modern spectrometers have variable acceptance areas of between about 50 µm and 1 mm, therefore the typical sample size (also for handling purposes) is in the range of 5 mm × 5 mm. The samples should be as smooth as possible in order to have a defined surface region for electron emission.

Usually the XPS measurements have to be done under UHV conditions. Remember that for a gas molecule at room temperature and a pressure of $10^{-4}$ Pa, and assuming a sticking probability of 1, the time for monolayer adsorption is only of the order of some seconds! Thus for minimum electron collision with the gas molecules, to avoid energy losses, and for minimizing the recontamination of the prepared surfaces, pressures in the range of $10^{-5}$ Pa should be reached at least. Therefore samples should generally have a low vapor pressure. Sample preparation with organic glue or epoxy resin should be avoided. Dedicated adhesive materials are available and can be used in minimum quantities for special preparation purposes. Powders may be impressed into ductile metal foils (In or Au). An alternative is the use of special UHV-compatible double-sided adhesive tape for sample fixing. Generally the samples should be outgassed in the fast entry chamber of the spectrometer for enough time, especially in the case of porous material. Biological samples may be freeze dried or, if sensitive to dehydration, the samples may be cooled in situ (by liquid nitrogen) during analysis.

Surface contamination is one of the main problems of sample preparation for surface analysis, unless the topmost natural surface layer itself is the topic of investigation (e.g. adhesion, catalysis, corrosion). In particular so-called “aventitious carbon” contamination from hydrocarbons plays an important role. Therefore clean conditions (gloves, tweezers, exsiccators, glove boxes, laminar boxes, etc.) and special cleaning procedures (rinsing in solvents, ultrasonic cleaning) should be routinely used. Despite such sample precleaning, contamination...
never can be avoided completely. Because even parts of monolayers of adsorbed species can negatively influence the surface-specific electron spectroscopic measurements, in situ cleaning is necessary in many cases. Medium-energy (1–5 keV) noble gas (Ar, Kr) ion sputtering is generally used; however, the ion bombardment induces morphological, structural and chemical changes in the surface. For the preparation of clean single-crystal surfaces sputtering–heating cycles are often applied. As an alternative, mechanical methods can be used to prepare fresh surfaces under UHV conditions if the sample properties and geometry are suitable. In principle, cleaving (of single crystals), scraping (with diamond-coated tools) or fracturing (special sample geometry, cooling with liquid nitrogen) may be used. Guidelines for specimen handling and preparation may be found in some reviews.\(^{(13,14)}\)

### 3 MEASURING STRATEGY

#### 3.1 Elemental Information

Information about the elements incorporated in the surface region is obtained from the measured BE values of the separate lines in the electron spectrum. Complete series of spectra are given in several publications (a standard reference book is that by Moulder et al.\(^{(15)}\)). Table 1 summarizes the BE values of the two most intense lines for each element. Note that XPS nomenclature uses the quantum numbers of the electronic core levels. In addition, note that the p, d and f levels are split by spin–orbit coupling into doublets with characteristic energy differences (in Table 1 energy splitting is given) and intensity ratios (1 : 2, 2 : 3, 3 : 4). Commonly Mg Ka (1253.6 eV) or Al Ka (1586.6 eV) are used for excitation because their natural line width is relatively small, photoelectron lines of all elements may be measured, and the relatively low KE of the measured photoelectrons allows high-energy resolution and good surface sensitivity. Only for special reasons, especially to obtain more bulk-specific information or to generate effectively higher energy Auger lines, X-ray sources with higher energy (e.g. Ag, Si, Ti, synchrotron radiation) have been used. The energy range in Table 1 is therefore restricted to the energy region up to 1400 eV.

As can be seen from this table there is a wide spread of energies which may be used for elemental identification. However, there may be spectral overlaps for specific combinations of elements, especially because Auger electron lines (not included in Table 1) are also excited by X-rays. The effect of overlapping Auger lines may be mostly avoided by an energy shift when changing the X-ray source. However, these XAES lines are often useful for both elemental identification and as a source of chemical information\(^{(16)}\) (section 3.2).

As an example, Figure 1 shows an Al Ka excited spectrum of a Sb\(_2\)O\(_4\) powder coated with a thin Au film for energy calibration. Besides a complete overlap of O1s and Sb2p\(_{3/2}\), one can see the Auger lines, C contamination, Au lines and satellite lines (from satellite energies of nonmonochromatized Al Ka radiation). Despite the dependence on the element (see Equation 3), the measured intensities vary systematically depending on the transmission function of the electron analyzer, here with \(1/E_k\) for the hemispheric analyzer used. An increasing background to lower KE (higher BE) comes from both nonelastic scattered electrons and the electrons excited by bremsstrahlung radiation from the X-ray source. Using a monochromatized source instead, the bremsstrahlung radiation and satellite peaks can be avoided, and additionally sharper peaks are obtained.

For quantitative analysis the BE scale has to be calibrated.\(^{(3,5,8)}\) This is done experimentally using the Fermi energy level of the spectrometer \(E_F = 0\) as a reference and by measuring (a) the well-defined peak positions of core levels of clean metals (e.g. Au4f = 84.0 eV, Cu2p\(_{3/2}\) = 932.67 eV) or (b) the valence band cut-off of metals with a high density of states near \(E_F = 0\) (e.g. Ni). Thus the basic Equation (1) is modified to Equation (2),

\[
E_k = h\nu - E_b - \Phi_S
\]

with \(\Phi_S\) as the work function of the spectrometer.

Concentration quantification is done using the intensity of a suitable (sufficient intensity, no spectral overlap with other elements) characteristic line as a measure for the number of atoms of a certain element in the analysis region. The basic relationship to calculate the total photoelectron intensity \(I_x\) of the core level peak \(i\) of element \(x\) for a homogeneous sample is given by Equation (3):

\[
I_{ix} = B\sigma_{ix}\lambda_{ix}T_{ix}n_x
\]

where \(B\) is the instrumental factor (X-ray flux, angular acceptance and total transmission of the spectrometer), \(\sigma\) is the photoabsorption cross-section for the level including asymmetry parameter, \(\lambda\) is the total electron escape depth for the core level energy and sample material, \(T\) is the transmission coefficient of the electrons through the surface, and \(n\) is the atomic density of element \(x\).

For exact calculations all these terms have to be assumed to be dependent on space coordinates and the appropriate integrals have to be solved.\(^{(8,10)}\)

For routine concentration calculations some assumptions have to be made:
Table 1 BE values (in eV, values rounded) for the two most intense XPS lines in the order of the elements of the periodic system (values are taken from Moulder et al.\textsuperscript{[15]})

Figure 1 Spectrum of an Sb2O3 sample. The sample was coated with a thin Au film for energy calibration.

- the analysis region should be a homogeneous mixture of the elements;
- the excitation probability of the core level used does not depend on the environment of the atom (low matrix effect);
- the electron background near the selected peak has to be removed before the intensity calculation is carried out.

The background subtraction can be done in several ways, from simple linear dependence to physically determined functions.\(^\text{17}\) Most used up to now is the method after Shirley\(^\text{18}\) which calculates an integrated background under the peaks. An example is given in Figure 2 for the complex Mo3d peak structure for Mo oxide.

Even if both the peak height and the peak area can be used as intensity values for calculations,\(^\text{15}\) only the use of peak area can be seriously recommended (see also X-ray Photoelectron and Auger Electron Spectroscopy). Peak area calculations lead to more realistic values, because the peak shape is changed by chemical effects (see Figure 2 and as discussed below) and will produce completely wrong results for components with different bonding states for the peak-height method. The peak area may be estimated by simple integration over the background or by using more sophisticated peak-fitting procedures (see section 3.2 and X-ray Photoelectron and Auger Electron Spectroscopy). Using these assumptions the simplest calculation for the concentration \(c\) is given by Equation (4):

\[
c_x = \frac{I_x}{S_x} \sum_i \frac{I_i}{S_i} \tag{4}
\]
where \( I \) is the intensity (peak area or peak height) and \( S_x \) is a relative sensitivity factor of the element \( x \).

In a first approximation the sensitivity factor is taken from an element or standard sample measured under equivalent conditions; alternatively, values from reference measurements for the appropriate analyzer type (using the same transmission function) or from theoretical calculations can be used. Analytical experience derived from working with a wide range of materials shows that, based on this simple strategy, a precision of about 10% can be reached; however, dramatic errors may occur if the sample is inhomogeneous within the range of electron escape depth.

Further improvements to the results may be obtained applying the following steps:

1. measuring element standards under exactly the same measuring conditions as for the unknown sample;
2. measuring similar well-defined compound standards;
3. performing escape depth correction and correction of changed atomic density (matrix correction);
4. simulation of concentration gradients if they are well known (overlayer correction).

A critical review of the limits of quantitative analysis is given by Powell and Seah which covers all the experimental, physical and mathematical aspects.

### 3.2 Chemical Information

One of the main advantages of XPS is the possibility of obtaining chemical information relatively easily by analyzing changes of the BE of the photoelectrons. This is possible because only one electron level is involved in the emission process, in comparison to AES where three energy levels have to be considered. The general shape of the photoelectron peaks, as shown in Figure 2 for a multicomponent peak, is determined by experimental and physical effects. First, the detected BE state is determined by the final ionized state of the emitting atom. Experimental broadening occurs typically as the result of the limited energy resolution of the spectrometer and the energetic width of the X-ray source, and may be described by a Gaussian function. Broadening due to the lifetime of the resulting hole is given by a Lorentzian function, and has to be added to the experimental broadening. Especially for metals, there is an asymmetric broadening to higher BE, generated by an interaction with unfilled electron levels of the valence band above the Fermi level (discussed in section 5.2). The resulting width is usually defined as full width at half maximum (FWHM) and, for optimum measuring conditions and sharp metallic lines (e.g. Ag2p3/2), is around 0.5 eV.

The exact energetic peak position of an emitted core-level electron on the BE scale now depends on the environment of the emitting atom. In single-element (e.g. single-crystalline or polycrystalline) materials used for standardization, this environment is defined by the same element as its characteristic bonding state and near-neighbor distances. In multi-element materials (alloys, oxides, carbides, etc.) this environment is altered and so is the electronic structure of the emitting atom. Several more or less empirical models were proposed during the early stages of XPS development, such as the "charge potential method", the "valence potential method", and the "equivalent cores approach". These models, summarized by Brundle and Baker and by Briggs, consider the chemical characteristics of the bonding partners as electronegativity, charge transfer or reaction energies. These original approaches have been further developed and extended, also using quantum mechanical methods. The principles of chemical shift estimation are discussed here for the charge potential method, which describes the change \( \Delta E \) in the BE of a core level by the changes in the electron density and the resulting potential changes:

\[
\Delta E = k \Delta q + \Delta V
\]

In Equation (5) \( \Delta q \) is the difference in valence charge of the atom (assumed to be located on a hollow sphere) multiplied by a factor \( k \), and \( \Delta V \) is the change in the effective potential assuming the surrounding atoms to be point charges. It is clear from the first term that the decrease in valence charge (e.g. oxidation) leads to higher BE values and the increase (e.g. reduction) to lower BE values.
parameter method. By measuring an additional XAES level (the three electron energy levels participating in the Auger process should be indexed \( lmn \)) of the same element and doing some approximations, the difference of this KE \( E_k(lmn) \) and the measured core level BE \( E_b(i) \) may be assigned to the parameter \( \alpha \) (Equation 6):

\[
\alpha = E_k(lmn) - E_b(i)
\]

and the change in this parameter may be determined by Equation (7),

\[
\Delta \alpha = 2 \Delta R_{ea}
\]

where \( \Delta R_{ea} \) is the so-called extra atomic relaxation energy, where static and dynamic relaxation have to be considered. This relaxation is associated with the polarization of a dielectric medium (here by the core-hole states), and thus the XPS experiment is closely connected with the chemical surrounding of the emitting atoms. However, the parameter \( \Delta \alpha \) is not influenced by surface charging (section 4.3) or other factors affecting BE reference levels. This can be a useful method for fingerprinting sample states. In a so-called Auger parameter plot (Figure 4) bonding types are characterized by clusters and may differ in both Auger parameter values and BE values.

For quantification of the described chemical shifts in sample series, mathematical methods may be used. The quantities of overlapping parts of core-level peaks may be estimated by peak-fitting procedures which are based mostly on nonlinear least-squares (NLLS) algorithms, as summarized by Gans. The starting parameters (number of peaks, energy separation, peak shape model, etc.) influence the results and require operator knowledge. Procedures are implemented in the manufacturers’ measurement software and in standard graphic software, which is critically reviewed by Siegbahn.

Figure 3 Dependence of B1s BE on electronegativity difference of the binding partners in several compounds. (Taken from S. Oswald et al.)

However, the second term must also to be considered; it has an opposite sign. This charge transfer situation has to be modeled using complex calculations; fast estimations are often possible using simple considerations of electronegativity differences as shown in Figure 3 for some boron compounds.

From this simple picture some general rules can be derived:

1. Most core levels of metals are shifted to higher BE in oxides (or fluorides, chlorides, etc.) because of the high electron affinity of O (F, Cl, etc.). These shifts will usually increase with increasing formal oxidation numbers.
2. The carbon line is shifted to higher BE in oxygen-containing compounds and to lower BE in carbides.
3. The core-level shifts in similar compounds will decrease with higher atomic radius, i.e. higher Z in the same group of the periodic table.

However, for real-world samples the specific electronic and crystallographic structure of the compound must always be considered. Thus, in practice it is not generally possible (although it is proposed from time to time) to apply BE reference energy values from a standard sample with well-defined valence states to an unknown compound for quantitative chemical state characterization.

Another approximation for the characterization of chemical effects is the so-called (modified) Auger effect. The core-level shifts in similar compounds will be modeled using complex calculations; fast estimations may be assigned to the parameter \( \alpha \) (Equation 6):

\[
\alpha = E_k(lmn) - E_b(i)
\]

and the change in this parameter may be determined by Equation (7),

\[
\Delta \alpha = 2 \Delta R_{ea}
\]

As shown in Figure 3 for substrate compounds and doing some approximations, the difference of this KE \( E_k(lmn) \) and the measured core level BE \( E_b(i) \) may be assigned to the parameter \( \alpha \) (Equation 6):

\[
\alpha = E_k(lmn) - E_b(i)
\]

and the change in this parameter may be determined by Equation (7),

\[
\Delta \alpha = 2 \Delta R_{ea}
\]

where \( \Delta R_{ea} \) is the so-called extra atomic relaxation energy, where static and dynamic relaxation have to be considered. This relaxation is associated with the polarization of a dielectric medium (here by the core-hole states), and thus the XPS experiment is closely connected with the chemical surrounding of the emitting atoms. However, the parameter \( \Delta \alpha \) is not influenced by surface charging (section 4.3) or other factors affecting BE reference levels. This can be a useful method for fingerprinting sample states. In a so-called Auger parameter plot (Figure 4) bonding types are characterized by clusters and may differ in both Auger parameter values and BE values.

For quantification of the described chemical shifts in sample series, mathematical methods may be used. The quantities of overlapping parts of core-level peaks may be estimated by peak-fitting procedures which are based mostly on nonlinear least-squares (NLLS) algorithms, as summarized by Gans. The starting parameters (number of peaks, energy separation, peak shape model, etc.) influence the results and require operator knowledge. Procedures are implemented in the manufacturers’ measurement software and in standard graphic software, which is critically reviewed by Siegbahn. X-ray Photoelectron Spectroscopy and Auger Electron Spectroscopy: Introduction.

Figure 5 demonstrates such a fitting for the MoO$_2$ sample given in Figure 2. The peak area ratio (Mo3d$_{3/2}$ : Mo3d$_{5/2}$ = 1 : 1.5) and the peak separation (here 3.1 eV) are fixed for the calculation. Three 3d doublets, which arise from different oxidation states, are necessary for good reproduction of the spectrum.

Changes occurring in a series of measurements may be typically classified by mathematical methods as linear least-squares (LLS) fitting, principal component analysis (PCA) or factor analysis (FA). The mathematical principles are summarized elsewhere. The LLS algorithms use standard measurements or typical sample states included in the measured data set as target spectra, whereas FA (commonly based on PCA algorithms) can detect chemical changes without (or with little) a priori information about the sample. Figure 6 demonstrates this
Figure 4 An Auger parameter plot for various copper compounds. Typical Cu valence states are shown. (Reproduced from Moulder et al. by permission of Physical Electronics, Inc.)

Figure 5 Demonstration of a multicomponent fit for the MoO₂ measurement given in Figure 2. Three 3d-doublet spectra are necessary for a good reproduction of the measured spectrum.

for a depth profile of an Re–Si–Re layer system. Interface phases connected with silicide formation, mainly induced by the ion sputtering effects, can be derived by such a mathematical procedure. The calculated spectra are characterized by both changes in intensity ratios and small energy shifts.

3.3 Local Information

Local information from a surface analytical technique such as XPS can be both depth information (because of the small information depth) and lateral information (using spectrometers with appropriate lateral resolution). The depth profiling methods can be classified into destructive (using depth erosion methods and lateral resolving spectroscopy) and nondestructive methods (only in the near-surface region).

For destructive depth profiling, medium energy (1–5 keV) noble gas (Ar, Kr) ion sputtering is mostly used. Depending on the ion source and the necessary raster size (typically 2 mm × 2 mm, determined by the
Figure 6 Depth profile of an Re–Si–Re–Si-substrate layer system (a) decomposed by FA into several phases (i.e. principal components). (b) The portions (loadings) of these several spectral components show strong changes in the interface regions. (c) The spectral shape of the components (scores) varies in peak energy/shape and peak area ratio and can be assigned to several silicide phases, in addition to Re and Si.

lateral resolution of the spectrometer) the erosion rates are in the range of 1–10 nm min⁻¹. Thus elemental depth profiles can be determined by sequential measurements of elemental intensities after several sputtering depth intervals. The depth resolution is determined by the escape depth of the electrons and sputtering effects, and lies in the range of 3–5 nm. In practice, the measuring depth is limited to approximately 1 µm, because the total measuring time is not only determined by the time of the sputtering cycles, but mainly by the time for sequential detection of the electron spectra. Effectively it depends therefore on the sputter-cycles-per-depth density, the number of measured elements, the desired spectral resolution, and the detection limit. As an example, Figure 7 shows a depth profile of a nonconducting Ba–Sr-titanate superlattice.

Figure 7 Kr⁺ sputtered (1.5 keV ion energy) depth profile of a Ba-titanate–Sr-titanate superlattice. The double layer thickness of the nonconducting structure is only 21 nm.

Depth calibration of the intensity versus sputtering time is difficult because the sputtering rates depend on both material (composition, microstructure) and the sputtering conditions (ions, angles, current density). The conversion of the sputtering timescale into a depth scale, if necessary, has to be done using depth (material)-dependent sputter rates for the particular experimental conditions. Single-layer sputter rates are usually determined for layers of known thickness or from crater depth measurements by surface profilometry. Alternative methodologies have also been discussed.

One of the main problems of depth profiling is the sputtering artifacts, which include preferential sputtering, atomic mixing, recoil implantation, bond breaking, amorphization, and crystallization. Preferential sputtering arises from the different sputtering yields of the individual elements in multicomponent samples. As a result, the surface composition (which is measured by XPS) is altered and does not reflect the
bulk (or layer) composition. Atomic mixing and recoil implantation additionally change the concentration gradients in the region influenced by ion implantation (up to 10 nm depth depending on ion sputtering conditions). These three effects can be modeled with reasonable results by Monte-Carlo computer simulations for a wide range of materials. The possible bond-breaking and structural changes limit the chemical information obtainable from depth profiling; however, in many cases ion depth profiling is the only method to get such information from thin layers or buried interfaces.

In summary, with ion sputtering the virgin (bulk) sample state is not necessarily being analyzed, and the nature and extent of damage strongly depends on the sample. Therefore, the influence of the sputtering effects has to be established for every new kind of material.

Nondestructive depth profiling techniques make use of the limited escape depth of the electrons (summarized in detail by Seah and Dench) and are therefore limited to the first few nanometers of the surface region. However, this region is often of particular interest in surface science (contamination, segregation, passivation, adsorption, etc.).

Angle-resolved X-ray photoelectron spectroscopy (ARXPS) is the most used technique. By sampling a series of measurements for different emission angles, the effective information depth \( d \) (for 95% of signal intensity) varies with the take-off angle \( \beta \) of the electron analyzer to the surface normal (Equation 8):

\[
d = 3\lambda \cos \beta
\]

The relative changes of peak area and peak shape give qualitative information on changes in both elemental composition and chemical bonding. Using appropriate surface layer models and mathematical algorithms one can estimate the surface layer structure.

A second method uses changes in the electron background coming from the nonelastic scattered electrons. The low-KE tail of a characteristic core level of one selected element is measured over a range of tens of electron volts, because these losses are characteristic of the depth distribution of this element in the surface region. Approximating the shape of this energy region with a computer program, by assuming a characteristic depth dependence (e.g. QUASES), allows the estimation of some typical parameters (thickness, concentration, nature of surface layer growth) of the surface structures.

Lateral information is rarely used in XPS because of the relatively poor lateral resolution (50–1 μm, depending on the instrumentation) at relatively long measuring times. Several experimental principles have to be considered. Traditionally, for large-area X-ray radiation, either a small-area lens (with deflection unit) prior to the electron analyzer or an imaging analyzer with channel plates is used; currently, focused X-ray sources with beam scanning or mechanical movement of the sample are also applied. Thus, line-scan measurements or mapping of surface areas can be obtained. Although most of the interesting phenomena regarding modern nanostructured materials are associated with nanometer-scale dimensions, some applications arise from the possibility of chemical imaging, which is the detection of complete spectra at each measuring point and spectral interpretation with respect to bonding changes. This is demonstrated in Figure 8 for a map of laser-treated Si3N4 ceramics.

Spectral analysis by FA (section 3.2) shows that in addition to Si–N/Si–O bonding (not distinguished at the energy resolution used, which was optimized with respect to reasonable measuring time for the small spot measurements) in the center of the laser spots Si–Si bonds were found.

**3.4 Valence Band Information**

Although early XPS work mainly dealt with the elemental and chemical information from core level...
photoelectron lines, valence band photoemission studies soon became increasingly important.\(^{(3,5,57)}\) This went hand in hand with the application of UV radiation as an excitation source, establishing the method of ultra-violet photoelectron spectroscopy (UPS). The valence band region (generally in the BE range from 0 to about 20 eV) covers the information about the outermost electron shell(s). The spectra in this region are usually rather complex, and therefore are less easy to interpret than the core-level peaks. In molecules the spectra reflect changes in the chemical bonding between the different atoms, of particular interest in organic materials.\(^{(58)}\) In the solid state the valence region has a band structure and the spectra characterize the density of the occupied electronic states (DOS), of considerable importance in the investigation of electronic transport properties in materials. Such band structure investigations may be complemented by the method of inverse photoemission spectroscopy (IPES) that measures X-rays emitted from electrons excited to the unoccupied density of states near the Fermi level.\(^{(16)}\) Valence band measurements with UV radiation are characterized by high excitation cross-sections, good energy resolution, and \(k\) (i.e. momentum) conservation (angular measurements at single crystals), by very high surface sensitivity (leading to problems with contamination), and by dependence on the unoccupied density of states at the final state energy.\(^{(15)}\) For excitations with conventional high-energy X-ray sources the intensities and energy resolution of the valence band measurements are weak; however, a direct measurement of the DOS is possible that does not depend on final-state effects.\(^{(9)}\) Because of the complexity of this topic only a small number of application examples are discussed in section 5.1.

### 4 APPLICATIONS FOR TYPICAL MATERIAL CLASSES

Many years of XPS usage have identified a broad spectrum of applications in nearly all scientific fields. The aim of this section is to give an idea of typical applications in several fields of natural and materials science, rather than a comprehensive account, together with some complementary techniques. Most examples are taken from recent work. Much of the pioneering work, taken from worldwide sources, has been well reviewed elsewhere.\(^{(3–5,8,16)}\)

#### 4.1 Metals and Alloys

Measuring the elemental composition of metal surfaces (layers or bulk material) is not a typical XPS task because elemental information for electrically conductive material can be obtained more quickly by other methods, such as AES. However, if chemical changes are of interest, XPS is of advantage, because the peak shifts are often much easier to interpret in terms of chemical bonding. Metals have been studied for a long time with respect of the chemical potential during alloying,\(^{(59–61)}\) work function measurements,\(^{(5,62)}\) and segregation phenomena,\(^{(63–65)}\) chemisorption studies,\(^{(66,67)}\) electrochemistry and corrosion science,\(^{(68–70)}\) or fundamental studies in catalysis.\(^{(71,72)}\)

#### 4.1.1 Segregation

Segregation of surfaces or interfaces is a phenomenon that strongly influences a material’s properties, such as brittleness or reactivity. Some XPS studies provide information about the segregant elements as well as information about their binding. Zhang et al.\(^{(73)}\) have shown for a W–Ni system how a combination of ARXPS and depth profiling can help to understand the chemical nature of the segregated surfaces. Danoix-Souchet et al.\(^{(74)}\) have observed Cu–Ni elemental and chemical changes during annealing – in addition to enrichment of the minor elements, a phase transition of the residual surface oxides from hydroxide to oxide could be found. Different MoSi\(_2\) composite materials were studied by Yi et al.\(^{(75)}\) by in situ fracturing. As shown in Figure 9, at the fractured surfaces an increasing amount of oxygen and Si–O bonding was observed. With information derived from scanning electron microscopy (SEM) of the fractured surfaces it was concluded that the grain boundaries were covered with SiO\(_2\). Boron segregation, forming borides, was also found.

#### 4.1.2 Interfaces

Thin interlayer regions or interfaces determine the properties of most layer systems and can be studied by depth profiling analysis. Metal–metal interfaces are often used in electronic contacts. Marinova et al.\(^{(76)}\) showed an example for an Al–Ni–Al on SiC contact system where both the elemental changes and peak shape changes connected with phase formation were explained on the basis of depth profiling measurements. Working with Pd–Co superlattices, Lesiak et al.\(^{(77)}\) determined the interface phases using a pattern recognition method.

For an Re–Si–Re–Si-substrate system, interface silicide phases were found and quantitatively extracted with help of FA,\(^{(56)}\) as shown in Figure 6. These phases were produced mainly by the ion sputtering process because they were not found in transmission electron microscopy (TEM) cross-sections of the virgin sample.
4.1.3 Corrosion

The investigation of corrosion is a typical XPS application because chemical information plays an important role. Research activity in this field ranges from basic research on well-defined surfaces to practical applications relating to construction materials. A review of the application of surface analytical techniques (including XPS) for corrosion investigation is given by Quaddakkers and Viefhaus. The XPS technique is characterized as a well-established method for the detection of corrosion products. Also useful is AES if applied with the high-energy resolution and with the higher lateral resolution for local analysis. The application of XPS in corrosion science covering many metals has been reviewed by McIntyre et al.

An example of a systematic study of the formation of passivation layers is given by Maurice et al. for the Fe–Cr–Ni system. Starting from the analysis of the natural oxide layer, the passivation layer formed in an electrochemical cell, for various exposure times, was studied ex situ in the XPS apparatus. Both depth dependence of the layer by ARXPS and chemical states (with respect to oxide and hydroxide state) were estimated by curve fitting (Figure 10). The investigations were accompanied by AFM (atomic force microscopy) measurements of the surface structure.

4.1.4 Catalytic Reactions

Catalysis can be studied with XPS in UHV only remotely. Gas adsorption investigations are of principal interest in this context. The motivation behind the use of surface analytical techniques is that in heterogeneous catalysis the mechanisms of interest are surface reactions. Most investigations in this field are dedicated to the study of the basic reaction mechanisms of catalytic processes. However, there is a strong interest in getting closer to more realistic conditions, which will be discussed later, in section 5.4.

Adsorption studies are usually performed under well-defined conditions using single-crystal surfaces. A typical example is given by Sandell et al. with a study of adsorption and reaction mechanisms of several gases (CO, NO, O2, CO2) on an ordered Pd–Mn single crystal surface prepared by Mn deposition on a Pd(100) single crystal and subsequent heating. Figure 11 shows changes in the Pd3d5/2 spectra during adsorption. The multiple components (see the curves at 20 L CO) were separated by peak fitting and assigned to several surface and bulk contributions.

Besides such adsorption studies, investigations using catalysts with more technological backgrounds were also done on precious metals (e.g. Pd). From the technological point of view, oxide catalysts are of more interest and will be discussed later in section 4.3.

4.2 Semiconductors

Because of the very small lateral structures of semiconductor devices, XPS is not a favored technique for failure analysis or process control. Thus, AES, as a surface analytical method with high lateral resolution, was used early in this field. XPS with its poorer lateral resolution is, nevertheless, used for investigations of new materials and their electronic properties, and for the development of new thin film deposition techniques. Some early examples are XPS studies of surface treatment and of new device technologies.

An important problem with semiconductors is the BE calibration. On one hand semiconductors have sufficient electrical conductivity for stable measurement using charged-particle methods, on the other hand the position of the Fermi energy EF, which is the energy reference in XPS (section 3.1), is not always well defined. In the undoped semiconductor EF lies in the middle of the band gap, whereas when doped EF is shifted to the acceptor or donor states at the edge of the valence band or conducting

The degree of shift depends on doping concentration and temperature. As discussed in detail by Egelhoff, energy shifts could be assigned to the influence of surface states occurring at the amorphized sputtered surfaces were corrected. Thus realistic BE values for Al and B could be obtained with respect to their chemical bonding in the SiC environment. It was shown that the Ar2p energy reference, from the noble gas atoms implanted by ion sputtering, was misleading in this case.

4.2.1 New Electronic Materials

The material SiC (discussed above) has been assessed as a candidate for high-temperature applications. Also of interest are the potential and problems for studying its electronic properties by XPS. Other material, such as InP, AlGaAs, or GeSi, are studied typically with respect to their surface and interface reactions. In InP, for example, the surface Fermi level is separated at cleaved surfaces for p- and n-type doping due to the Fermi level pinning. Figure 12 shows how this changes as a result of exposure to several gases and subsequent heating.
Figure 11 CO adsorption on Pd. The adsorption started from a clean Pd(100)-Mn-c(2×2) surface. This ordered surface structure is equivalent to the (100) surface of an ordered Pd3Mn bulk alloy. Coverage using 1 and 20 L (1 L = 1 Langmuir, a dose of 10−6 Torr s) of CO completely changes the spectra. By heating, the CO coverage can be removed. (Reprinted from: A. Sandell, A.J. Jaworowski, A. Beutler, M. Wiklund, ‘Adsorption and Reactions on a Surface Alloy: CO, NO, O2 and CO2 on Pd(100)-Mn-c(2×2)’, Surf. Sci., 421, 116–134 (1999), with permission of Elsevier Science.)

Chemical core level shifts after treatment with S2Cl2 were examined by Peisert et al., including the use of the Auger parameter method. Figure 13 shows peak shape changes during heating that have been estimated by peak fitting.

Investigations of new deposition methods allow the study of film formation or new interface properties.

4.2.2 Contact Structures

These play an important role in determining electrical properties and microelectronic technology. Rintamäki et al. showed the selective oxidation of Te at the interface for a PdTe alloy contact on ZnSe during interface formation, i.e. during its preparation. A Pd/ScSi Schottky structure was measured with depth profiling, including peak shape analysis. Silicide formation could be observed during heating.

4.2.3 Surface Contamination

The characterization and minimization of surface contamination is also an application of XPS. Moon et al. studied a cleaning procedure for organic contamination. The effectiveness of the cleaning process, especially when using UV radiation, can be observed through analysis of the C1s peak (Figure 14).

The XPS technique has been used to optimize etching processes so as to obtain low defect densities, and for studying Fermi level pinning for doped Si wafers. Quantitative analysis of such thin overlayers and of the material underneath is assisted by mathematical methods. These have been further developed for ARXPS, including the effects arising from surface topography.

4.3 Insulators

Surface analytical techniques that use charged particles, such as AES or SIMS (secondary ion mass spectrometry), generally do not work for insulators because their electrical nonconductivity results in surface charging. However, XPS uses electromagnetic waves for excitation and is therefore favored for the investigation of surface properties of insulators. These insulators include inorganic material such as various oxides, oxidic catalysts, glasses, and ceramics.

The emitted electrons will also lead to surface charging of the sample, a feature that has to be considered in any investigation. In most cases, however, the use of nonmonochromatized X-ray excitation leads to relatively small and stable energy shifts at the BE scale. This is
Figure 13 Results of surface treatment of InP(001) with S2Cl2 at room temperature (RT) and with subsequent heating. The BE scale is referenced to the valence band maximum (VBM) and not, as usually, to \( E_F \) to minimize the influence of band gap changes on the results. (Taken from H. Peisert et al.\(^{99} \))

because secondary electrons emitted from the X-ray tube effectively stabilize the surface charging situation. External flood guns, which produce low-energy electrons, can be used for charge stabilization. This is necessary especially when using monochromatized X-ray radiation.\(^{118} \) This approach also minimizes the shift observed when using nonmonochromatic radiation. Another method is to use a metallic grid (e.g. from TEM) or metallic aperture on top of the insulating sample for charge exchange. The problems with surface charging are complex, and depend on sample geometry, differential charging, and peak shape changes.\(^{119} – 121 \)

For quantification of chemical information, the residual shift of the BE scale has to be corrected with respect to a reference BE. There are several traditional methods:\(^{89} \) (a) adventitious carbon contamination, C1s at 285 ± 0.2 eV, although there can be relatively broad peaks from various C–X species;\(^{122} \) (b) internal reference lines of well-defined energy; (c) implanted noble gas, mostly Ar, although errors may arise from electronic interaction with the surrounding chemical environment; and (d) artificial mixtures/overlayers, where the problems are homogeneity, contamination, and particle size. A promising method is the deposition of Au nanoparticles from a suspension onto the surface (Au4f = 84.0 eV).\(^{123} \) Such referencing techniques have also been successfully used for automatic shift correction of measurement series\(^{124} \) (such as depth profiles with varying surface conductivity) prior to further data analysis by FA or LLS.

Insulator analysis is a wide-ranging application area, because of the many material classes involved. It includes materials with covalent bonds (e.g. oxides, nitrides, and carbides) and with ionic bonding (e.g. chlorides and fluorides).

4.3.1 Catalysts

Catalysts, discussed in section 4.1, are often applied as their oxides. Mathematical methods (curve fitting, FA, deconvolution) are used for quantification of small peak shifts or peak shape changes in the XPS spectra.\(^{125} – 128 \)

In many investigations standard spectra are compared with spectra of chemical states formed during treatment of the catalytic surfaces. Davidson et al.\(^{125} \) investigated changes of Ni oxide species on Ce-based material in comparison with NiO, Ni2O3, and Ni(OH)\(_2\) standard materials. A transformation from Ni(OH)\(_2\) to NiO during heating in air was observed. The chosen BE reference was C1s at 285 eV.
4.3.2 Ceramic Materials

These are investigated to identify changes in their surface properties. Figure 15 shows a laser-ablated surface of an Si$_3$N$_4$ ceramic sample. In this example large-area Nd:YAG radiation in a halogenic atmosphere was being tested for future micromachining applications. A depth profile of the changed surface region of about 2 µm depth was measured. Because of changing conductivity, different peak shifts were observed during depth profiling. An automatic correction with respect to Ar2p was done, using the method proposed by Oswald et al.\(^\text{56,124}\) which confirms peak shifts of up to 6 eV. The result, which was derived by FA, shows three compounds with different depth profiles: PC1 is surface oxifluoride, PC2 is an Si-rich interlayer formed from molten and decomposed silicon nitride, and PC3 is bulk silicon nitride.\(^\text{56}\) However, the resulting spectra (scores) do not have ideal peak shapes because of the relatively high charging shifts, in which there is a possibility of differential charging. The decomposition of silicon nitride as observed in PC2 was also found during local laser radiation in the center of the laser spots. A chemical map of a sample area about 2 mm × 2 mm measured with 100 µm lateral resolution is shown above in Figure 8 and discussed in section 3.3.

Ion-implanted silicide ceramic has been investigated to detect modification of its tribological properties.\(^\text{129}\) Line scan and depth profile measurements established that the wear reduction mechanism is not solid lubrication, as previously assumed, but comes from structural changes in the surface region.

4.3.3 Oxide Materials

Mostly oxides are insulating materials. However, the electrical properties of oxides vary, depending on structure, from wide-gap insulating, to semiconducting, to superconducting properties at low temperatures.

As an important dielectric material silicon oxide has been studied with respect to its surface stoichiometry.\(^\text{130}\) Several methods (peak area calculation, lineshape fitting, Auger parameter) were compared, showing the Auger parameter method as being easy, fast and very reliable. This fact has been confirmed for many oxide systems.\(^\text{131,132}\) Cluster formation and oxidation of Ge,
implanted in silicon dioxide films after thermal treatment, were studied by XPS and the redistribution processes followed by the characteristic peak shape changes that occurred. These were probed further by FA.

Stoichiometric SiO$_2$ is a very stable oxide and is used as a passivation layer. It is also very stable during ion sputtering procedures, whereas other oxides show marked changes after ion sputtering. Okude et al. demonstrated this for tin oxide thin films. Using ion beam sputtering with an oxygen beam, however, XPS has proved that stoichiometric SnO$_2$ films can be prepared.

As a semiconducting oxide doped with other components, SnO$_2$ is used for electrical applications such as gas sensors and indium–tin oxide (ITO) transparent contacts. Examples of gas sensors are given by various authors. Figure 16 shows XPS results for a Pt-doped material. Peak fitting procedures show that several compounds are formed at the surface, changing the electrical properties.

It is necessary to know the formal valence states of oxides in order to study their properties and structure. To derive this information from XPS measurements, many problems have to be considered. Although BE reference values from external standards can be used, there may be variations arising from the BE not being in correlation with a formal chemical valence. Another problem is that the valence states at the sample surface may differ from bulk, as a result of contamination or preferential oxidation. By way of illustration, Figure 17 shows spectra for Mo compounds prepared under different conditions. The species Mo$^{6+}$ and Mo$^{4+}$ in the MoO$_3$ and MoO$_2$ (scraped) samples are well defined. In the Mn$_2$Mo$_3$O$_{14}$ (scraped) sample Mo should also be Mo$^{4+}$ (2MoO$^-$/3MoO$_2$) but the peak is significantly separated from MoO$^-$ due to the MnO environment. It may be that this is an intermediate oxide state that also occurs at the MoO$_2$ surface (shoulders to high BE side). Rapid oxidation to Mo$^{6+}$ is found after short exposure to air of the Mo$^{4+}$-containing samples.

Barr has shown that analysis of the oxygen O1s peak shift can give good information about the metal–oxygen bonding. This is also true for O2s information about TiAlO films.

Complex oxides are of interest for new electronic applications and as oxide superconductors. The depth profile of the Sr–Ba titanate superlattice shown in Figure 7 can only be measured while using a charge compensation (here a low-energy electron flood gun). Despite the sputtering effects, relatively sharp depth profile tails point to sharp interfaces. Calculations show that the interface roughness is about 2 nm. High $T_c$ superconductors (especially with a critical temperature, $T_c$, higher than 77 K, the boiling point of liquid nitrogen) are materials attracting much basic research and are of technological significance. Padalia et al. have reviewed XPS studies of YBCO oxide superconductors. The main topic of these investigations is the detailed study of the Cu2p spectra including the satellite structures typical of the active Cu–O superconductor layers in comparison to Cu oxide standard samples.

In this context it should be mentioned that radiation damage may also occur during XPS measurement of particular samples (see section 4.4). This may arise...
Figure 17 Spectra of different Mo-containing oxide single crystals (a) scraped under UHV conditions and (b) after short treatment in air. Relatively well defined valence states (the sharp peaks) are found on the scraped samples. Oxidation to Mo$^{5+}$ occurs immediately in air.

from both secondary electrons from the X-ray window (nonmonochromatized source) and from photoelectrons and Auger electrons emitted from the sample (also with monochromator). Iijima et al. discussed this for the partial reduction of CuO surfaces in different experimental conditions.

4.4 Polymers and Organic Materials

The materials discussed here can be insulating, semiconducting, or electrically conducting. The central topic is material systems based on carbon and its compounds.

This covers a wide range of materials, including new polymers widely used as construction and functional materials, organic materials including problems of biocompatibility, and new inorganic carbon-based materials such as diamond or a$C-H$ (hydrogenated amorphous carbon).
layers, carbon nitride or the conjugated carbon systems (fullerenes, nanotubes, etc.). Because of the relatively low damage by X-rays to polymers or organic materials, XPS was applied to this field early in its development. Clark et al. did a lot of experimental and theoretical work in the 1970s (e.g. on core levels) which covered a wide range of materials (summarized by Clark and by Dilks). The usefulness of valence band information to distinguish different functional groups was also recognized early on. In biology and medicine XPS also found application.

Investigations of changes in the C1s peak are the main interest. During the early stages of XPS development a wide spread of BE was reported from 281 eV (carbide) to 293 eV (fluorine). However, these material systems consist mainly of the light elements (C, H, N, O, etc.) and thus are sensitive to radiation damage. Toth et al. discussed this for polyvinyltrimethylsilane with respect to surface ion cleaning and electron flooding for charge compensation. The example in Figure 18 shows results from CN layers demonstrating that only a very small ion dose (Ar+, 3.5 keV, 2 min, 0.3 µA, 2 mm × 2 mm) leads to drastic peak changes and a strong degradation of nitrogen.

If handled carefully, XPS and UPS provide one of the most powerful methods for analysis of such sensitive materials, in contrast to electron beam techniques such as AES and EPMA (electron probe microanalysis). Because of its surface sensitivity XPS is mostly used for investigation of surface treatments or interface properties in compound materials. An overview of XPS applications to polymers up to the late 1980s is given by Briggs.

### 4.4.1 Polymers

Polymers and their surface treatments is one main area of XPS application. The cleaning of polyester products is discussed by Briggs et al. Figure 19 demonstrates how the complex C1s spectrum of a commercial product can be fitted to the base material spectrum of the polyester and to the spectrum of residuals of a Permalose polymer. This was also confirmed by time-of-flight/secondary ion mass spectrometry (TOF/SIMS) measurements. The thickness of the Permalose contamination is estimated to 2.4 nm from attenuation length consideration.

Similar surface modification experiments have been published with respect to plasma polymerization.

---

**Figure 19** (a) Fingerprint spectra of a polyester-based fabric. The peak overlay procedure shows it contains both (b) the PET base spectrum and (c and d) Permalose polymer spectral components. (Taken from Briggs et al.)

![Image of Figure 19](image-url)
surface segregation\textsuperscript{159} and laser treatment\textsuperscript{160} for different polymers. Mähl et al.\textsuperscript{161} have dealt with the fitting of multicomponent C1s peak structures to polymers. Polymer–metal interfaces are of growing interest. During evaporation of aluminum on polyaniline films Lim et al.\textsuperscript{162} studied the reaction mechanism by evaluating peak shape changes of the N1s peak. Similar work has been done for the metals Cu, Ti,\textsuperscript{163} Cu, Fe, Al,\textsuperscript{164} Al,\textsuperscript{165} and Cr.\textsuperscript{166} Riga et al.\textsuperscript{167} used valence band spectroscopy to identify the specific structure of well-oriented polyethylene mats after adsorption on Au. Structural information can also be derived for Langmuir–Blodgett films.\textsuperscript{168} Adhesion phenomena are closely connected with the interaction of organic polymers and metal oxides.\textsuperscript{169}

Conducting and doped polymers have been studied by valence band XPS or UPS to establish changes of electronic structure and thus conducting or doping mechanisms.\textsuperscript{170–172} Salanek\textsuperscript{173} has summarized investigations on conjugated polymers. As an example the UPS valence band spectra (see section 5.1) of Figure 20 show how the electronic properties of a polymer may be controlled by sodium doping. The charge carrier density near Fermi energy is increasing with dopant concentration, leading to higher conductivity.

The possibilities of chemically imaging for polymers were demonstrated by Forsyth and Coxon.\textsuperscript{174} Using the different C1s energies for C–C, C–O, and C–F as the source for mapping, a surface contamination of polytetrafluoroethylene could be detected with a lateral resolution below 5 µm.

4.4.2 Biomaterials

Investigations in this area mostly include the problem of dehydration in a vacuum. Little reported work deals with the measurement of hydrated samples at low temperatures.\textsuperscript{175} More successful are investigations into naturally dehydrated materials, such as wool,\textsuperscript{176} bone, teeth, or cellulose-containing material from plants including wood.\textsuperscript{177} Also demonstrated in this work was the combination of XPS and TOF/SIMS, which is often used for polymer analysis.

The chemical changes of flax fibers after NaOH treatment have been studied.\textsuperscript{178} The flax fibers were fixed on the sample holder for analysis with UHV-compatible adhesive tape; however, a longer outgassing period was necessary. Strong oxidation with a peak shift to C–O was found. Other examples in this field deal with proteins on surfaces\textsuperscript{179,180} and aerosol particles.\textsuperscript{181}

Many applications concern biocompatible surfaces\textsuperscript{182,183} because of their increasing importance for modern medical implants. The sol–gel technique seems to be promising for oxide interlayer deposition on Ti. Cirilli et al.\textsuperscript{184} have compared sol–gel prepared and conventional plasma-sprayed Ti oxide layers. By studying the O1s peak shape it was found that in the sol–gel prepared oxide layer fewer OH and H2O components are incorporated, which indicates that these films consist of better defined stoichiometric oxides.

4.4.3 Inorganic Carbon-based Materials

The most studied feature here is the ratio of sp\textsuperscript{3} to sp\textsuperscript{2} hybridization, because this controls the material structure. As demonstrated by Meral et al.,\textsuperscript{185} for diamond-like carbon films using XPS with high-energy resolution, the sp\textsuperscript{2} (284.4 eV, graphite) and sp\textsuperscript{3} (285.2 eV, diamond) spectra may be separated directly and quantified by curve fitting. Figure 21 shows that the proportions of two components depend on the power density used for the laser deposition technique. This separation was used to detect the sp\textsuperscript{3} content, which had to be maximized for optimum layer properties. For the carbon nitride system with respect to the theoretically predicted C\textsubscript{3}N\textsubscript{4} phase, the sp\textsuperscript{2} to sp\textsuperscript{3} ratio of the C–N bondings plays an important role (sp\textsuperscript{3}-like carbon bonds are expected in C\textsubscript{3}N\textsubscript{4}). As concluded by Boyd et al.,\textsuperscript{186} for the C–N system, the sp\textsuperscript{2} (C1s = 285.9 eV, N1s = 400.6 eV) and sp\textsuperscript{3} (C1s = 287.0 eV, N1s = 398.8 eV) bondings are also well separated. From Figure 18, it can be seen that this reactively
sputtered layer consists mainly of sp² carbon–nitrogen bonds and that the degradation due to sputtering leads to a substantial increase of C–N bonding by preferential sputtering of N.

One area of basic research is connected with conjugated carbon systems, namely the fullerenes, nanotubes, and onions (so-called because of their appearance as multiwalled carbon spheres). Photoelectron spectroscopy is used to study changes in the electronic structure during doping or phase formation. Using core-level measurements, Poirier et al. observed structural changes depending on dopant concentration. Figure 22 demonstrates this feature for Rb doping.

Valence band measurements are used to study the occupied states near the Fermi energy. For RbC₆₀ changes were found in the lowest unoccupied molecular orbital (LUMO) states, depending on phase structure. Additional studies combining photoemission measurements with electron energy loss spectroscopy (EELS) are providing new information about both occupied and unoccupied electronic states in this new class of materials.

4.4.4 Spectral Databanks

Spectral databanks should become useful for polymers and organic materials because of the great variability in their structure and chemical bonding (i.e. for fingerprint investigations). As already in place for static SIMS for several years, collections of XPS spectra are now being offered. However, the expectations should not be too high because the spectral shape, especially for complicated systems, depends on many experimental factors, such as X-ray source parameters, take-off angle, spectrometer type and pass energy, and BE reference/charge neutralization. The reliability of such systems depends on the analytical problem and has to be assessed by the individual user.

For some time XPS spectra, including sample and measuring parameters, have been published periodically in a specialist journal. A database specializing in organic polymers has also been published. Two commercial databases in electronic form come from the National Institute of Standards and Technology, USA (with free access after year 2000), and from

Weaver, ‘X-ray Photoemission Investigations of Binary and Ternary C₆₀ Fullerides of Na, K, Rb and Cs’, *Phys. Rev. B*, 47(15), 9870–9877 (1993), Copyright 1993, the American Physical Society.)
XPS International, Japan. Most activities also are offered on the Worldwide Web: (ojps.aip.org/ssso/), (www.nist.gov), (www.xpsdata.com), (www.uwo.ca/ssw), (www.specs.de); naturally, this trend will increase in coming years.

A free database from the Surface Analysis Society of Japan is available, including a data processing system from the Internet (sekimori.nrim.go.jp). This database can be complemented with own spectra. In this context it should also mentioned that there exists a project for implementing a common data format for the transfer of spectral data between different machines in surface science.

5 SPECIAL METHODOLOGIES

5.1 Valence Band Spectroscopy

The method of valence band spectroscopy (section 3.4) is an integral part of the XPS method. However, it has a particular role in terms of chemical analysis, because chemical bonding is directly involved in the valence band structure and the valence spectra are quite complex. Therefore, no direct insight into the elemental composition of the investigated sample is possible. Consequently, some of its applications are discussed here in this separate section. Because of the higher excitation probability UV radiation from discharge lamps (He I D21: 21.2 eV, He I D40: 40.8 eV) is often used. UPS has been used for the investigation of light elements, gases, small molecules or hydrides, oxidation/chemisorption processes, and conducting polymers, often in conjunction with XPS results. Valence band investigations (also done by XPS) are useful for the identification of different structures in polymers where the C1s core-level peak shows no change. These UPS results have been compared with DOS calculations for simple metallic systems. Using approximation calculations for the molecular electronic structure commonly based on multiple scattered wave methods (usually described as Xα calculations) valence band spectra estimations are possible for larger molecules. The combination of such measurements and DOS calculations are performed routinely to confirm theoretical considerations. Figure 23 gives an example for different dimers of doped fullerenes.

5.2 Loss Spectroscopy

Because the X-ray-induced photoelectrons or Auger electrons have to cross the surface region before they are emitted into the vacuum, nonelastic scattering may influence their energy. If due to the structural, electronic or chemical nature of the material one specific energy (region) of these losses is dominating, additional peaks may be identified and used for analysis. Processes for such additional (secondary) structures are very complex and are described in more detail elsewhere. In this section, although not completely correct, all additional structures at the low-KE (high-BE) side of the photoelectron peak are discussed briefly as losses:

- **Plasmon losses** – mainly occurring on metals, these are collective interactions with the conduction band electrons, and are divided into bulk and surface plasmons. These losses may also be discussed in connection with conventional EELS investigations.

- **Shake-up satellite lines** – may be observed if a significant part of the emitting atoms is in the final state, not in the ionic ground state but in an excited state (valence electrons excited in higher unfilled levels).

- **Asymmetric core levels** – are found in metals due to the excitation of conducting band electrons into unfilled bands above the Fermi energy (similar to Figure 23 Valence band spectra for (C₉₅N)₂ (full circles) and (Rb₄C₆₀)₂ (open circles) in comparison with density-of-states (DOS) calculations (solid lines). The normalized curves of the calculated DOS and the measured photoelectron intensities can then be used for qualitative comparison of the doping mechanism. (Reprinted with permission from: T. Pichler, M. Knupfer, M.S. Golden, S. Haffner, R. Friedlein, J. Fink, W. Andreoni, A. Curioni, M. Keshavarz-K, C. Bellavia-Lund, A. Sastre, J.-C. Hummelen, F. the shake-up process). In non-metals vibrational broadening may be observed.

- **Multiplet splitting** – may occur if the atom has unpaired electrons in the valence level. Because of the residual spin the final ionic state may have a different energy and an additional splitting may be observed.

In connection with the main XPS features an analysis of such structures can lead to additional information. Cremer et al.\(^{132}\) have discussed the possibilities of loss analysis for ceramic material. There is also a direct comparison of XPS and EELS loss analysis.

A classic example of loss spectroscopy is boron nitride,\(^{210}\) because its cubic and hexagonal modifications may not be distinguished by XPS core-level analysis, but these are clearly identified by changes of the \(\pi-\pi^*\) shake-up satellite. By way of illustration, Figure 24 shows spectra of hexagonal BN and cubic BN material.

### 5.3 Photoelectron Diffraction

As well as the nonelastic processes discussed in section 5.2, naturally elastic scattering of the emitted electrons is a principal process in the surface region. Because of the wave nature of the electrons in the quantum-mechanical description, diffraction and interference phenomena are to be expected. By measuring the peak intensity for the BE of a core-level photoelectron peak in the hemisphere above the sample, diffraction patterns can be observed if the surface region is well ordered (e.g. for single crystals or epitaxial layers). One of the first detailed studies was the work on copper by Fadley et al.\(^{50}\) In practice the sample is usually rotated with respect to the analyzer (and the X-ray source) for such measurements.\(^{50,211}\)

Photoelectron diffraction (PED) is a complementary technique to extended X-ray absorption fine structure (EXAFS) investigations.\(^{9,212}\)

Band dispersion properties can be investigated using UV excitation and photoelectron energies near the Fermi energy with angular dependent measurements. Using a small energy window, Fermi surface mapping can be done – as a spherical cut through the three-dimensional Fermi surface.\(^{213}\) This work demonstrates the powerful combination of X-ray and UV excited techniques. As an example, Figure 25 shows diffraction patterns of Au to study the growth mode on Bi-2212 (\(\text{Bi}_{2}\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}\)) superconductors where a 8.4 nm thick Au film was deposited onto Bi-2212. The measured Au4f diffraction pattern (Figure 25a) can be explained by a structural

(Taken from Aebi et al.\(^{213}\))
model (Figure 25b) of two Au(111) domains rotated by 180°. This was concluded from Figure 25(c), which shows a very similar hexagonal pattern to that in (a). This pattern was reconstructed from an overlay of two Au(111) diffraction patterns as measured on Cu(111) (Figure 25d), but rotated by 180°.

Other work deals with structural effects in GaAs-based epitaxy. As shown theoretically by Nefedov et al., it should also be possible to learn about overlayer thicknesses by investigating the shape of the diffraction patterns.

5.4 In Situ Preparation, Special Equipment

Because of the problems that can arise concerning surface contamination, sample preparation is an important issue. Classical preparation techniques such as sequential sputtering and heating (for single-crystal preparation), scraping, fracturing or cleaving (for bulk or grain-boundary investigations) can often be used directly in the analysis chamber under UHV conditions. The trend towards more realistic experimental conditions for surface and interface modification has led to the use of special preparation chambers, to protect the analytical system from damage or contamination. Such chambers are separated from the analysis chamber by gate valves. This makes it possible to conduct procedures such as layer deposition with various deposition techniques, heating to higher temperatures, treatments with reactive gases and even electrochemistry without affecting the XPS measuring system. For contamination-free transfer of the sample after treatment, the preparation chamber is evacuated to UHV.

Electrochemical experiments and other solid–liquid interaction studies have been tried, using specialized equipment to deal with the non-UHV conditions. Another way to avoid contamination is the use of special transfer chambers. Such equipment can be used for changing samples between different vacuum processes or to extract them from experiments under glove-box conditions.

Efforts to obtain X-ray sources with higher brightness have led to the use of synchrotron radiation. Using special monochromators, it is possible to use monoenergetic X-rays over a wide energy range, in addition to the high-intensity bremsstrahlung radiation preferably used in XAES. Thus, the equipment for surface analysis has been installed at individual beam lines, or the experimental teams go with their own equipment to the beam line. Synchrotron experiments are often focused on microscopic studies, real-time measurements, or resonant photoemission studies.

6 COMPARISON WITH OTHER TECHNIQUES

Comparison with other techniques is a difficult task, because of the wide range of methods and their specifications. For the confident solution of most problems a skillful combination of several techniques is usually necessary.

As a basis for comparison with other analytical techniques, the main characteristics of standard XPS are as follows:

- **Features** – high surface sensitivity (2–5 nm), elemental information from core levels, detection limit about 0.1 atom %, chemical information from peak shifts, sputter depth profiling, direct measurement of band structure (valence band).

- **Advantages** – high surface sensitivity, chemical information easily to understand, nonconducting material possible, low sample damage.

- **Disadvantages** – low lateral resolution and thus low depth profiling sputter rates, problems with surface contamination, difficult preparation of bulk states, difficult BE scale calibration at insulators and semiconductors.

The techniques outlined below and other surface-related techniques are summarized regularly in several monographs.

6.1 Auger Electron Spectroscopy

AES is the most complementary technique to XPS because of the similarity of the physical process employed. The Auger electrons are usually excited by a focused electron beam (3–10 keV), but X-ray excitation is also possible. In principle, AES has the same surface sensitivity and detection limits, although it is used more routinely for surface elemental analysis. High lateral resolution (50 nm) and faster depth profiling is possible. Chemical shifts are also present here, but they are more complicated to interpret. The AES technique is not suitable for insulating samples. Often multitechnique equipment AES/XPS is available on one machine using the same electron analyzer.

6.2 Secondary Ion Mass Spectrometry

This technique, which uses ion sputtering and detection of the emitted secondary ions from the surface, is a method for local trace analysis (ppb range). Its characteristics include lateral resolution down to 50 nm (with liquid metal ion sources), monolayer depth resolution (additionally broadened by mixing effects), and detection of all elements (including H), and isotope separation is possible.
Quantification is difficult because of strong matrix effects. With additional postionization, using secondary neutral mass spectrometry (SNMS), better quantification may be obtained. In static mode (low ion dose) and with TOF (time-of-flight) mass spectrometry (offering high mass resolution and mass range), molecular information may also be obtained; SIMS is often used in connection with XPS for polymer analysis.

6.3 Atomic Force Microscopy and Raster Tunneling Microscopy
These are methods for studying the local surface structure. Atomically sharp tips mounted on a very thin cantilever are used in close contact with the investigated surfaces. Mechanical (i.e. atomic forces) or electrical (i.e. tunnel current) interaction is used as the detected signal. Fine positioning of the cantilever is done by piezo ceramics and the resulting deflections are measured with laser optics. Structural information of the surfaces down to atomic resolution is routinely available. Using special measuring modes (modulation, special tips), additional local (mechanical, magnetic, chemical) information may be obtained. These methods are often used in connection with XPS to derive additional molecular and structural information. Atomic force measurements are also possible in the atmosphere or even in liquids.

6.4 Low-energy Electron Diffraction and Reflection High-energy Electron Diffraction
These are both electron diffraction techniques that can be used for surface structure investigations during sample cleaning (single crystals), thin-film preparation (epitaxy), and adsorption studies. They mainly differ in the impact energy and in the impact angle of the electrons. Because of the very low penetration depth of one or two atomic layers, low-energy electron diffraction (LEED) applications mainly concern adsorption or single-crystal studies. In reflection high-energy electron diffraction (RHEED) the penetration depth is larger and may be controlled additionally by the reflection geometry. This method is used also in combination with glancing angle X-ray diffraction.

6.5 Ion Surface Scattering
This is a rarely used method with extreme surface sensitivity (topmost layer). The elastic scattering of light ions (typically He\(^+\) or Ne\(^+\) in the energy range from 500 eV to a few keV) depends on the masses of surface elements. An energy spectrum of the scattered primary ions, depending on the angular situation, is recorded. The surface damage is low, but not always negligible. The main applications are surface segregation and adsorption studies. It is usually combined with XPS because of the use of the same analyzer (with changed polarity). Ion surface scattering (ISS) is sometimes called low-energy ion scattering (LEIS).

6.6 Infrared Spectroscopy
In surface analysis, infrared spectroscopy is useful for investigation of the bonding of molecules on the surface. Two methods should be mentioned here: Fourier-transform infrared spectroscopy (FTIR, based on the absorption of the radiation) and Raman spectroscopy (based on characteristic inelastic scattering of light). Lateral information may be obtained using focused laser radiation. Surface analysis is done preferably using reflection geometry. Vibrational infrared modes give information on the bonding types in UHV, under any gas pressure or in the liquid phase, which allows in situ experiments even in electrochemical cells.

6.7 Electron Energy Loss Spectroscopy
This has been discussed earlier in this article and is not a typical surface analytical technique. However, it is often used in connection with valence band XPS and UPS for basic studies of electronic band structure. Because high-energy electrons are used, EELS is commonly done in transmission on thin samples (typically 100 nm) in both standard transmission electron microscopes (mainly for local element or chemical analysis) and special UHV equipment (mainly for local element or chemical analysis) and special UHV equipment (mainly for local element or chemical analysis) and special UHV equipment (mainly for local element or chemical analysis) and special UHV equipment (mainly for local element or chemical analysis) and special UHV equipment (mainly for local element or chemical analysis).

6.8 Rutherford Backscattering Spectroscopy
This is a widely used nondestructive depth profiling method with very good quantification capabilities using the scattering of high-energy (as opposed to ISS), low-mass ions (typically He\(^+\) in the 1 MeV range). The depth information has to be recalculated from the broadening of the elemental scattering peaks on the KE scale. The method has no lateral resolution (typically in the millimeter range, or using special beam collimators down to some micrometers) and is not suitable for light elements with high-Z samples.

6.9 Glow Discharge
Glow discharge optical emission spectroscopy (GDOES) and glow discharge mass spectrometry (GDMS) are developing from bulk-only to depth-profiling methods because of new source design and fast data collection. Relatively low ion energies from the glow discharge enable good depth resolution; however, the surface sensitivity is limited by high erosion rates and high sample temperatures. No lateral information is available.
7 OUTLOOK

Photoelectron spectroscopy is an analytical technique that, during its four decades of use, is assuming an increasingly important role among the surface-related techniques. Both experimental and theoretical aspects are now well understood. For routine analysis further development in terms of quantification, promoted by the revolution in computer techniques, is envisaged – more sophisticated escape depth models, calculation of chemical shifts and valence band features, use of large spectral data banks. Demands on future applications will be connected with new trends in biotechnology, environmental research, life sciences, biology, and nanotechnology. New instrumentation is likely to address wishes for lower spatial resolution, higher brightness, good energy resolution and variable X-ray energies, and will be closely connected with synchrotron radiation and X-ray optics.

2 Detection Methods in Atomic Spectroscopy
Abbreviations and Acronyms
References

Atomic spectroscopy (also termed atomic spectrometry) is one of the oldest and most well established of the analytical methods. Its roots can be traced to very early observations in which the presence of specific salts in a chemical sample imparted characteristic colors to a luminous flame. Atomic spectrometry is perhaps the most prominent and widely used of the family of methods employed for elemental analysis.

All methods for elemental analysis, including atomic spectrometry, exploit quantized transitions characteristic of each individual element. For example, X-ray fluorescence spectrometry utilizes inner-shell electron transitions. Because inner-shell electrons are not involved in bonding, the transitions they undergo are perturbed very little by the presence of nearby atoms, by chemical bonds, or by the external environment of an atom. As a consequence, X-ray fluorescence spectra consist of narrow spectral lines that are indicative of each element. Moreover, the sample can be in virtually any state – solid, liquid, or gas. However, X-ray fluorescence spectrometry has its shortcomings. Detection limits are seldom below the level of one part per million in either a solid or liquid, it is difficult to measure elements of low atomic number, and X-radiation emitted by one element can be absorbed by certain others present in the same sample. A consequence of this last factor is rather severe matrix (interelement) interferences. That is, the signal that is observed from one element depends not only on its concentration, but also on the concentration of other elements in the sample.

Neutron activation analysis (NAA) is another approach for elemental analysis that relies upon discrete transitions typical of each element. In this case, however, the transitions are in the atomic nucleus. Thus, they too are unaffected by chemical bonding or by the presence of other nearby atoms. Unfortunately, most samples do not lend themselves immediately to analysis by means of nuclear transitions, since they do not contain appreciable amounts of naturally radioactive nuclei. As a consequence, the samples must be “activated” by placing them in an intense flux of slow neutrons. The resulting activated nuclei can then be employed for chemical analysis. However, the requirement of a slow neutron source limits the widespread applicability of the method.

Unlike these alternative methods, atomic spectrometry utilizes quantized transitions in the conveniently accessible ultraviolet, visible, and near-infrared regions of the electromagnetic spectrum. As a result, the spectroscopic instrumentation is relatively inexpensive, readily available, and easy to use. Of course, it is valence electronic transitions that occur in these spectral regions. For narrow-band, characteristic spectrum to be generated, each atom must be isolated from all others, so the transitions are not perturbed by neighboring atoms or by bonding effects. If this requirement is not met, the resulting spectra are representative more of molecules or molecular fragments than of atoms themselves.

Accordingly, the underlying requirement for all atomic methods of analysis is that a sample be decomposed to the greatest extent possible into its constituent atoms. Ideally, this atomization step should be quantitative; there should be no residual bonding in the gas-phase atomic cloud. Anything less than complete atomization will understandably yield lower sensitivities in any atomic method. Even more importantly, changes in the fraction of atomization from sample to sample or from sample to standard will cause errors in calibration. Thus, it is less important that complete atomization be achieved than that the fractional atomization be extremely consistent. To the extent that this condition is not met, interelement (matrix) interferences in atomic spectrometry can be extremely troublesome.

It is not surprising, then, that a consistent theme in the history of atomic spectrometric analysis is a search for improved methods of atomization for samples in solid, solution, or gaseous form. It is therefore appropriate that we consider such systems in some detail here.

1 SYSTEMS FOR ATOM FORMATION IN ATOMIC SPECTROSCOPY

Schemes for the atomization of various samples have followed several traditional paths. The most common first step is to dissolve the sample if it is not already in solution form. Although this step is an inconvenient and often time-consuming one, it also offers a number of important benefits. First, after a sample is dissolved, the principal constituent in the sample solution is the solvent. Consequently, most sample solutions look more or
less the same and similarly resemble standard solutions that are prepared. Second, samples in solution form are relatively easy to handle and lend themselves readily to automation. Third, sample solutions permit relatively simple and straightforward background correction, simply by use of a solvent or reagent blank. Lastly, other constituents can readily be added to sample and standard solutions to simplify such procedures as standard additions (spiking) and internal standardization.

Among the methods widely employed for automation of the solution-introduction step in atomic spectrometry is flow injection analysis (FIA). Unlike many other automation schemes, FIA can be employed not only to introduce solution samples directly, but to dilute them in an automatic and predictable fashion, to mix the sample solution with other reagents, to exploit standard-additions and internal-standardization approaches, and to speed up the sample introduction process. Through use of FIA, it becomes possible routinely to employ sample solution volumes as low as 10 μl, to reduce build-up on sprayers and other equipment in an atomic spectrometric system, and to improve precision. Some of the benefits and capabilities of FIA are described in Flow Injection Analysis Techniques in Atomic Spectroscopy.

Once a sample solution is prepared, it can be converted to free atoms in several alternative ways. One is to pipette a small aliquot of the sample solution into an electrothermal atomizer (ETA) such as a graphite furnace. This method is discussed in greater detail in Graphite Furnace Atomic Absorption Spectrometry. In the graphite furnace, the solvent is first evaporated from the sample at a moderate temperature. The furnace temperature is then raised so organic material is ashed, and the temperature next increased rapidly to the point where the sample is vaporized and ultimately atomized. Not surprisingly, the furnace temperature and the sample composition are extremely important in ensuring the efficiency and consistency of this atomization.

A second path to the atomization of solution samples is through a nebulization (spraying) process. In simple terms, nebulization serves to increase the surface area of the solution sample, so solvent evaporation (desolvation) can proceed more rapidly and so the resulted dried solute particles can be volatilized better. This scheme, which is probably the most common in analytical atomic spectrometry, is employed in flame atomic absorption, flame emission, and plasma emission spectrometry and is detailed in Flame and Vapor Generation Atomic Absorption Spectrometry and Inductively Coupled Plasma/Optical Emission Spectrometry. Once formed, droplets in the nebulized spray are sent into a high-temperature environment such as a chemical flame or flowing rare-gas plasma. There, desolvation and solute-particle vaporization take place, and the resulting vapor converted more or less efficiently into free atoms. Indeed, the environment in these discharges is often hot enough that many of the atoms that are formed wind up as positively charged ions. Also, the environment in these atomization sources is often energetic enough to yield strong emission from either the freed atoms or their ionic counterparts. Correspondingly, this general scheme lends itself well to a number of different detection approaches that will be discussed shortly: atomic emission spectrometry (AES), atomic absorption spectrometry (AAS), atomic fluorescence spectrometry (AFS), and atomic mass spectrometry (AMS).

For some elements, it is possible to employ a more straightforward means of generating free atoms. In the case of mercury, for example, free atoms can be formed simply by the chemical reduction of inorganic mercury in solution to the free atomic form. The neutral mercury atoms can then be driven from solution merely by passing an appropriate carrier gas (for example, air or argon) through it. The liberated atoms, present in a relatively cool environment, can then be measured alternatively by such techniques as atomic absorption or AFS.

For other elements, a chemical reaction will yield not free atoms but rather other volatile species that can be dissociated into free atoms at moderate temperatures. The most common example here is the use of a chemical reduction to form a stable hydride of such elements as tin, antimony, and arsenic. As in the case of mercury atoms, these volatile hydrides can be driven from solution by bubbles of an appropriate gas, which will carry them into a moderate-temperature flame or furnace for atomization. Once formed, those atoms can then be measured by atomic absorption, atomic fluorescence, or certain other spectrometric methods. These schemes are discussed in greater detail in Flame and Vapor Generation Atomic Absorption Spectrometry.

Naturally, it would be desirable in many cases to be able to analyze solid samples directly. Even more beneficial in special cases would be the possibility of measuring sample concentrations in a solid on a three-dimensional spatial basis. Some methods employed for sample volatilization and atomization have been aimed at exactly that goal.

Of such methods, the best established employs a glow discharge, detailed in Glow Discharge Optical Spectroscopy and Mass Spectrometry. In a glow discharge, ordinarily operated at pressures in the range of 1 Torr, the sample surface is bombarded by energetic rare-gas ions, usually of argon. Because of this steady bombardment, the surface is eroded on a layer-by-layer basis. Thus, atoms freed from the surface as a function of time are taken from successively deeper layers within the sample. Recording the spectrometric signal as a function of time then permits a “depth profile” of the sample to be obtained. In early work, glow-discharge devices were
applicable only to conductive solid samples because of the need to impart a negative charge to the sample surface, in order to attract argon ions to it. More recent developments, however, have shown it possible to utilize radiofrequency-sustained discharges for the same purpose; such discharges permit the depth-resolved analysis of nonconductive samples as well.

In recent years, intense laser beams also have been exploited for depth resolution. Unlike the glow discharge, however, a laser beam can be focused to discrete, extremely small spots on the sample surface, so that not only depth resolved but also laterally resolved information can be obtained. In its most straightforward version, the laser is employed not as an atomization source but rather as a sampling device, as is described in greater detail in **Laser Ablation in Atomic Spectroscopy**. In recent years, the importance of the laser’s wavelength and power density on the ablation process has been characterized more fully and has led to a burgeoning array of applications. Significantly, sample material ablated by a laser can be fed into any of several sources for further atomization. The most attractive combinations have been between laser ablation and either inductively coupled plasma (ICP) AES or ICP mass spectrometry.

A more direct approach to solid-sample analysis, described in **Laser-induced Breakdown Spectroscopy**, is to exploit the laser beam not only for sample vaporization but also to generate a plasma in which the sample vapor can be atomized, excited, and ionized. This technique, termed laser-induced breakdown spectroscopy (LIBS), is applicable to samples of many types and can also be applied to surfaces that are relatively remote from both the laser and the spectrometric measurement equipment.

Some sources employed in atomic spectrometry are not as good at generating atoms as they are at exciting or ionizing them. The microwave-induced plasma (MIP), discussed in **Microwave-induced Plasma Systems in Atomic Spectroscopy**, typifies such sources. Interestingly, the MIP (like some other spectroscopic sources) is well removed from local thermodynamic equilibrium. That is, the source appears to have several temperatures that are linked not by equilibrium processes but rather by kinetically controlled events. Thus, the temperature that would define the energy distribution of electrons moving in a MIP is generally much higher than the temperature that would pertain to the motion of heavier particles such as rare-gas atoms or ions. An important consequence of this dis-equilibrium is that features driven by the electrons (most importantly from our standpoint, ionization and excitation of atoms) are extremely efficient whereas other events that are controlled by gas-kinetic (thermal) operations are less efficient. Because solvent evaporation and solute-particle vaporization occur mostly through these latter thermal events, they are not efficient in a MIP.

The result of this situation is that the MIP is exceptionally useful for exciting and ionizing atoms, but that it cannot as readily effect vaporization. In fact, many MIP systems tolerate only a small loading of solvent vapor before they are visibly perturbed. The MIP therefore finds an important role in atomic spectrometry in the dissociation of gas-phase samples and in the production of atomic emission and mass spectra. It is therefore particularly attractive as a source for detection of gas chromatographic effluents, of gas-phase species generated by a chemical-based hydride-formation apparatus, or for atoms volatilized from an auxiliary source such as a carbon furnace.

### 2 Detection Methods in Atomic Spectroscopy

Once atoms are in the gas phase, they can be probed by any of several spectrometric techniques, including AES, AAS, AFS, AMS, coherent forward scattering spectrometry, photothermal deflection spectrometry, atomic magneto-optic rotation spectrometry, and several others. Of these alternatives, the most common have become atomic absorption, atomic emission, and AMS.

AAS dates from the earliest observations by Fraunhofer of dark lines in the sun’s spectrum and, as an analytical method, from the pioneering work by Walsh and by Alkemade and Milatz in 1955.\(^1\,2\) It has become a workhorse in atomic spectrometric analysis, in large part because of the simplicity of the instrumentation that it requires. To perform atomic absorption requires only a primary light source, usually a hollow cathode lamp, an atomization cell such as any of those described in the preceding paragraphs, a spectral isolation device such as a monochromator, an appropriate photodetector, and associated electronics. Working curves are usually constructed in the form of a Beer’s-law plot familiar from molecular spectrophotometry. However, for Beer’s law to be followed closely (that is, for linear calibration curves to be obtained), the band of detected radiation must be narrower than the atomic absorption line that is being measured. Because atomic absorption lines are extraordinarily narrow, the primary light source (hollow cathode lamp) must emit a band of light that is at least as narrow. It is for this reason that the hollow cathode lamp was chosen. Significantly, this choice also simplifies the measurement, since spectral lines emitted by the hollow cathode lamp are typical of the element being measured and are naturally locked onto the narrow atomic absorption lines of interest. Thus, spectral mismatch is almost impossible and spectral interferences are relatively uncommon because of the narrowness of the spectral lines that are being probed.
Unfortunately, it is not particularly convenient to measure more than one element at a time by means of AAS. There is a necessary straight-line geometry among the primary light source (hollow cathode lamp), the atom cell (flame or furnace) and the detection equipment. This alignment makes it difficult to incorporate more than a single source into the system; because each hollow cathode lamp emits efficiently the spectrum of only one, two, or three elements at a time, measuring additional elements requires substituting a new hollow cathode lamp. Although recent advances have been made in continuum-source atomic absorption, even those arrangements are somewhat limited: continuum sources that extend well into the important ultraviolet region of the spectrum are not widely available. Moreover, when furnace atomization is employed, it is often necessary to employ a different temperature program for each element.

One of the problems encountered in AAS is the generation of a broad-band spectral background. This background arises from absorption caused by residual molecules or molecular fragments in the atom source and by scattering from smoke or other airborne particulate matter. Because a hollow-cathode lamp is utilized as a light source, this molecular absorption or scattering cannot be distinguished from atomic absorption, since it simply attenuates the beam. If left uncorrected, this “nonspecific absorption” then makes element concentrations appear to be higher than they really are.

Not surprisingly, nonspecific absorption is more of a problem when furnace atomizers are employed than when a chemical flame is utilized. In a furnace, a dense smoke cloud often arises during atomization of the sample, whereas in a chemical flame the particulate matter is more thoroughly volatilized. Nevertheless, it is considered to be prudent to employ some form of background correction with either a furnace or flame atomizer.

Several alternative schemes for background correction have been developed for AAS and are covered in some detail in Background Correction Methods in Atomic Absorption Spectroscopy. The most common of these schemes, termed “continuum-source background correction” is particularly ingenious and is the first of such methods to be developed. It exploits the spectral difference between narrow-band atomic absorption and broad-band molecular absorption or scattering. However, two sources are required, a hollow cathode lamp and an auxiliary continuum source, usually a deuterium arc lamp. Still, it remains the most widely used method.

Another technique for background correction in atomic absorption utilizes the Zeeman effect. The Zeeman effect is a splitting of atomic lines that occurs when the atoms are present in a magnetic field. Accompanying this spectral splitting is a change in polarization of the spectral lines that are generated. By use of appropriate instrumentation, it is possible to distinguish atomic absorption from the background features. Although no auxiliary source is required, a magnetic field and polarizers usually are.

Another approach employed for background correction in atomic absorption utilizes a pulsed hollow cathode and is similar in concept to the continuum-source procedure. In essence, the same hollow cathode lamp is used as both a narrow-band and broad-band source. The broad-band spectrum arises from spectral line broadening that occurs at unusually high hollow cathode operating currents.

In contrast to AAS, AES is inherently a multielement procedure. In a high-temperature flame or plasma (such as the ICP), atoms are not only formed extremely efficiently, but also they generate intense atomic emission. The emission is isotropic and also occurs from all elements at the same time. It is therefore possible to perform multielement determinations simply by means of a multichannel detection system. Multichannel devices are routinely being introduced that employ two-dimensional spectral dispersion coupled with two-dimensional arrays of detector elements of unprecedented sensitivity and low noise.

Like AES, AMS is inherently a multielement approach. Moreover, AMS can provide information about isotopes present in a sample. Although a small spectral shift occurs in atomic emission spectra because of the “isotope effect”, for most elements in the periodic table that shift is too small to be detected with a conventional spectrometer. In contrast, AMS can readily distinguish one isotope from another; one of the important applications of AMS has therefore become the measurement of isotope ratios in various kinds of samples.

AMS offers also the benefit of extraordinarily low background levels. In the simplest sense, this low background results from the fact that ions in a mass spectrometer can possess energies that are considerably greater than energies corresponding to photons in the ultraviolet or visible region of the spectrum. For a photon of such low energy to be detected with high sensitivity requires naturally that the detector be very sensitive and accordingly sensitive to thermal effects. Thermal noise generated in such detectors therefore makes it more difficult to observe the atomic transitions of interest. In contrast, detectors employed in mass spectrometry can be considerably less sensitive to thermal noise because they can employ detection surfaces with a high “work function”. The result is background count rates in AMS that can be below one count per second, whereas background count rates in AES are of the order of $10^4$ cps. The result is that typical detection limits in AMS are lower than those in AES by a factor of 100 or so. Recent manufacturers’ literature suggests that it is now routinely
possible to measure solution concentrations in ICP mass spectrometry at the level of one part per quadrillion or so.

For the ultimate in sensitivity, however, none of the above-mentioned techniques can better AFS. Indeed, a number of AFS studies over the last decade or so have demonstrated the detection of single atoms of a desired element. The reason for this extraordinary sensitivity is quite straightforward: in AFS, each atom can be detected many times, since it can be excited over and over again. Each time the atom emits a photon, it can be re-excited by an incident beam of photons, probably from a laser. In contrast, detection in AMS is usually destructive, so there is only a single chance to observe each atomic ion. Although AES also offers the opportunity to collect several photons from each atom, the background levels are usually high enough that it is difficult to distinguish the few photons an atom emits from others that a detector registers.

Several properties of a laser make it useful not only as a source for AFS, but for other measurements in atomic spectrometry as well. These features are documented in greater detail in Laser Spectrometric Techniques in Analytical Atomic Spectrometry. In short, the laser can deliver light to a sample very effectively, so it can be used not only as a source for laser sampling (laser ablation) and LIBS, as indicated earlier, but also as a source for atomic magneto-optic rotation spectrometry, for AAS, and for other more exotic measurements. To date, the widespread acceptance of these alternative methods has been limited by the cost and complexity of current laser systems. However, recent advances and engineering developments suggest that such impediments might be overcome in the future.

From this brief narrative, it should be clear that atomic spectrometric analysis is not only an extremely important area of chemical analysis, but also one that continues to evolve rapidly. Over the past decade, the nature of instrumentation for atomic spectrometry has changed dramatically. Benchtop units are now available that measure virtually the entire atomic emission spectrum of a complex chemical sample at once. Similarly, alternative kinds of mass spectrometric instrumentation (quadrupole mass filters, sector-field instruments, time-of-flight mass spectrometers, ion traps, and Fourier transform mass spectrometers) have been applied to AMS. These alternative approaches enable samples to be analyzed with unprecedented speed, accuracy, and precision. They permit isotope ratios to be determined on samples having elemental concentrations below 1 ppt and at a speed that would have been considered impossible only a few years ago. Because of this rapid development, the reader should consider the treatments in this section to be an excellent introduction to the field, but that continuing acquaintance will be necessary to keep abreast of ongoing developments.

Background Correction
Methods in Atomic Absorption Spectroscopy

Margaretha T.C. de Loos-Vollebregt
Delft University of Technology, Delft, The Netherlands

1 INTRODUCTION
AAS is based on the absorption of element-specific primary source radiation by analyte atoms. If part of the radiation is absorbed by molecules or lost due to scattering, a higher gross absorbance is measured. The difference between the net absorption of the analyte atoms and the measured gross absorbance is called background absorbance. Background absorption and scattering effects have much more serious effects on the results produced in electrothermal atomization atomic absorption spectroscopy (ETAAS) than flame atomic absorption spectroscopy (FAAS).

The amount of incident light deflected or absorbed by nonatomic species must be measured to obtain the correct, net absorbance of the analyte atoms only. Perfect background correction can be obtained only when the background absorbance measurement corresponds exactly in space, time and wavelength with the atomic absorbance measurement. Since exact coincidence of all three parameters is obviously impossible, it is customary to give priority to the equality in space and to make the difference in time and/or wavelength as small as possible. Although molecular absorption and radiation scattering are both broad-band phenomena, there is no spectral range where constant background attenuation can be guaranteed.

In all background correction systems two measurements are made. The total or gross absorbance is measured at the wavelength of the resonance line emitted by the hollow cathode lamp (HCL). The background attenuation is then subtracted from the measured analyte absorbance to obtain the analyte absorbance. There are several ways in which the nonatomic absorption at the resonance wavelength can be estimated, including two-line background correction, continuum-source or deuterium lamp background correction, Zeeman background correction, pulsed lamp or Smith–Hieftje background correction and wavelength-modulation correction methods. The principle of each method, the instrumentation and applications are discussed. Continuum-source background correction is widely used in FAAS and ETAAS, whereas Zeeman background correction and pulsed lamp background correction are often preferred in ETAAS.

1 INTRODUCTION

AAS is based on the absorption of element-specific primary source radiation by analyte atoms. If part of the radiation is absorbed...
Scattering of primary source radiation from non-volatilized particles much smaller than the wavelength ($\lambda$) follows Rayleigh's law. The intensity of the scattering depends on the wavelength as $\lambda^{-4}$, so that short wavelengths are scattered more than long wavelengths. Scattering is directly proportional to the number of scattering particles per unit volume and to the square of the particle volume. Consequently, radiation scattering occurs more strongly with increasing particle size. In FAAS, well-designed nebulizers and spray chambers are used and therefore virtually no unvolatilized particles pass into the optical beam. In graphite furnace AAS, considerable numbers of particles can be observed. They may arise from organic sample materials during the pyrolysis step or from volatilized inorganic materials that condense in the cooler parts of the atomizer. Small solid particles can also appear owing to boiling, sputtering and incomplete vaporization. Broad-band molecular absorption of radiation is caused by molecular species formed or vaporized in the atomizer during the atomization step, particularly alkali and alkaline earth metal halides. Sharp fine structure of the vibrational bands in electronic spectra of the molecules can be superimposed on broad-band background absorption. The effects of molecular absorption in FAAS have long been recognized. The CaOH$^+$ band has a maximum near the barium resonance line at 553.6 nm. Molecular absorption spectra of a number of halides, nitrates and sulfates have been reported. As an example, Figure 1 shows the continuous dissociation spectra of SO$_3$ and of SO resulting from volatilization of sulfates in a graphite furnace, reported by Massmann and Güçer$^{(1)}$ and Newstead et al.$^{(2)}$ Massmann and Güçer$^{(1)}$ also measured emission and absorption spectra resulting from the CN system with band heads at 386.2, 387.1 and 388.3 nm using nitrogen as the inert gas in ETAAS. Background absorption and scattering effects have much more serious effects on the results produced in ETAAS than in FAAS.

The amount of incident light deflected or absorbed by nonatomic species must be measured to obtain the correct, net absorbance of the analyte atoms only. In electrothermal atomization the spatial and temporal distribution of the atoms and the background-generating species may be entirely different.$^{(3)}$ Perfect background correction can be obtained only when the background absorbance measurement corresponds exactly in space, time and wavelength with the atomic absorbance measurement. Since exact coincidence of all three parameters is obviously impossible, it is customary to give priority to the equality in space and to make the difference in time and/or wavelength as small as possible. Although molecular absorption and radiation scattering are both broad-band phenomena, there is no spectral range where constant background attenuation can be guaranteed.

In all background correction systems two measurements are made. The total or gross absorbance ($A_{\text{measured}}$) of the atoms and the nonatomic species is measured at the wavelength of the resonance line emitted by the HCL. The background attenuation ($A_{bg}$) is then subtracted from the measured absorbance to obtain the analyte absorbance ($A_{\text{analyte}}$) (Equation 1):

$$A_{\text{analyte}} = A_{\text{measured}} - A_{bg}$$

(1)

There are several ways in which the nonatomic absorption at the resonance wavelength can be estimated.

### 2 TWO-LINE BACKGROUND CORRECTION

In the two-line background absorption approach, the total absorbance is measured at the resonance line emitted by the HCL and the nonspecific absorbance is measured at a nearby line of the lamp, where the analyte atoms do not absorb.

Two-line background correction was first proposed by Willis,$^{(4)}$ using a nonresonant analyte line or a line from an element that is emitted by the source but not present in the sample. Argon or neon lines can also be used. Alternatively, another source, of an element which is not found in the sample, can be inserted for the background measurement. The background spectral character must be known to be the same at the second line as it is at the primary line and therefore the closer the second line is to the primary line, the better will be the correction. These
conditions cannot be met for all elements and all matrices. In some wavelength regions, the steep slope of molecular absorption bands makes it difficult to find a nonabsorbing line close enough to the analyte line to ensure an accurate background correction. The atomization conditions for sequential measurements should be as similar as possible, even if an appropriate nonabsorbing line is available from the primary source itself. Dual-channel AAS instruments offer the possibility of simultaneous measurement at two lines. The monochromator of the first channel is set to the chosen absorption line for the analyte element and the second channel monochromator is set to the chosen line for the background correction. The signal-handling system of the instrument subtracts the absorbance measured in the second channel from the absorbance signal measured in the first channel. Two-line background correction went into practice earlier than the other methods. However, it has not been widely used. Lines have been recommended for background correction for the most commonly determined elements. It is important that the chosen line should be close to the line of the analyte element. Because the absorption signal from background scatter varies with wavelength and increases with decreasing wavelength, the background correction error may become substantial at wavelengths below 220 nm if the line chosen is more than 1 nm from the analyte line. The use of an automatic system, chopping rapidly between both lines, is essential if the system is used with an electrothermal atomizer because measurements made on two successive furnace cycles are unlikely to show the same background signal.

3 CONTINUUM-SOURCE BACKGROUND CORRECTION

3.1 History

To improve the sensitivity of AAS, Koirtyohann and Picket used a 40 cm long, 10 mm i.d. tube that was heated in a hydrogen–oxygen flame, providing a much longer effective absorption path than was previously used in the more conventional burners. They observed that, at the higher sensitivities, absorption by matrix salts at the wavelength of an elemental resonance line can cause significant errors and proposed to use a hydrogen lamp to correct for matrix absorption. In fact, this background correction system is still widely used to correct for background absorption in FAAS and ETAAS.

3.2 Principle

The gross absorbance $A_{\text{measured}}$ is the sum of the atomic absorbance of the analyte atoms $A_{\text{analyte}}$ and the background attenuation $A_{bg}$. The gross absorbance is measured with the narrow HCL emission line of the element at the selected specific wavelength of the resonance line. An estimate of the background absorbance is obtained as an average over the spectral band-pass of the monochromator using a continuum-source of radiation, e.g. a hydrogen lamp or deuterium lamp in the ultraviolet (UV) wavelength region or a tungsten lamp in the visible part of the spectrum. The width of the atomic absorption line is about 100 times smaller than the band-pass of the monochromator, so that the analyte absorption of the continuum-source radiation can be neglected.

3.3 Instrumentation

For the correction of background attenuation, Koirtyohann and Picket used a dual-channel system in which the radiation from an HCL was passed alternately with the radiation of a continuum hydrogen lamp through the flame. Nowadays, a deuterium lamp is most frequently used as the continuum-source. Figure 2 shows the basic schematic configuration of a continuum-source background correction system for FAAS. By using lamp pulsation or by means of a rotating chopper with a sector mirror, the radiation from the HCL with intensity $I_{D2}^0$ and the radiation from the deuterium lamp with intensity $I_{D2}^0$ are passed alternately through the atomizer. After passing the monochromator, both radiation beams reach the same detector and the net atomic absorbance is derived.

The operation of the continuum-source background correction system is explained in Figure 3(a–f). The monochromator separates the resonance line from the emission spectrum of the element-specific HCL. The width of this line is a few picometers. From the deuterium lamp emission spectrum the monochromator isolates a band equivalent to the spectral band-pass, usually 0.2–1 nm. The primary intensities of the two beams of radiation are equalized to obtain $I_{HCL}^0 = I_{D2}^0$. When analyte atoms absorb HCL radiation, the intensity $I_{HCL}^0$ decreases with an amount corresponding to the atom concentration. Naturally, $I_{D2}^0$ is also attenuated at the resonance wavelength, but since the half-width

![Figure 2](image)

*Figure 2: Schematic configuration of a continuum-source background correction system. Radiation from the HCL (HCL) is passed alternately with radiation from the deuterium lamp (D2).*
Figure 3 Mode of operation of a continuum-source background correction system. (a) The line emission spectrum of the HCL and the continuum emitted by the deuterium lamp; (b) the monochromator isolates the resonance line from the spectrum of the HCL and passes a band of radiation from the deuterium lamp corresponding with the spectral band-pass; (c) the intensities \( I_{\text{HCL}} \) and \( I_{\text{D}_2} \) are equalized; (d) for atomic absorption by the analyte element \( I_{\text{HCL}} \) is attenuated by an amount corresponding to its concentration whereas \( I_{\text{D}_2} \) is not significantly attenuated; (e) broad-band background attenuates the intensity of both sources to the same degree; (f) atomic absorption by the analyte in addition to the background attenuates the HCL intensity further as in (d) whereas the deuterium lamp intensity is not further attenuated. (Reproduced by permission of Wiley-VCH from B. Welz, Atomic Absorption Spectrometry, 2nd edition, VCH, Weinheim, 1985.)

of the atomic absorption line is about 5 pm whereas the continuum has a width equal to the spectral band-pass of 0.2–1 nm, the absorption of continuum radiation by the analyte atoms can be neglected. If nonspecific attenuation of the radiation occurs, whether through scattering or molecular absorption, both radiation beams will be attenuated to the same extent since background attenuation is usually a broad-band phenomenon. In continuum-source background correction it is assumed that the background is constant over the observed spectral range, i.e. the attenuation of \( I_{\text{D}_2} \) is measured as the average over the spectral band-pass and used for background correction at the wavelength position of the analyte absorption line. If the background attenuation is not continuous within the observed spectral range, positive or negative background correction errors will occur.

The two lamps are observed by the detector alternately in time. Instrument electronics separate the signals and compare the absorbances from both sources. A net absorbance will be displayed only when the absorbance of the two lamps differs. Since the background attenuates both sources equally, it is ignored. Analyte atoms absorb the HCL radiation and negligibly absorb the broad-band continuum-source emission and it is therefore still measured and displayed as usual without background correction. Most modern AAS instruments permit almost simultaneous measurement of the uncorrected signal or background signal and the corrected signal. The speed of the background correction system should be high enough to follow the fast transient signals in ETAAS (see section 7.2).

Background correction with a continuum-source has some disadvantages. The alignment and superposition of the HCL or electrodeless discharge lamp and the continuum-source are critical. Both lamps are located at different positions in the instrument, the shape of the beams is different and the intensity distribution in the beam is not the same. Even if it is possible to align the beams exactly, different absorption volumes may be irradiated. The application of two light beams requires a more complicated optical system and in many instruments double-beam operation is available to compensate for intensity changes of the lamps. The deuterium lamp emits sufficient radiation in the short wavelength range from 190 nm to 330 nm, whereas a halogen lamp is used for background corrections above this range. In general, the signal-to-noise ratio (S/N) is worsened through the use of two radiation sources and the more complicated optical system that is used to measure their intensities. If a continuum-source is used outside its optimum range, the radiant intensity of the line source must be reduced, leading to further deterioration of the S/N. Finally, it should be noted that the principle
of operation of continuum-source background correction limits successful use to continuous background absorption only.

3.4 Applications

Many commercial AAS systems are based on deuterium lamp background correction. In FAAS and hydride generation AAS it is the most widely applied background correction system. It is fully adequate for all applications of FAAS, except in some very unusual circumstances. During methods development, background correction is considered. In many applications, there is no need to use background correction at all. In general, in the lower UV wavelength region (<220 nm) background correction is required.

Background correction systems employing continuum-sources are incapable of correcting the background attenuation of electronic excitation spectra because these comprise many narrow lines. The actual background correction that is required depends on the degree of overlap between the elemental spectral line and the individual molecular rotational lines. An example is the absorption line of gold at 267.6 nm that lies exactly in the middle between two rotational lines of indium chloride so that the actual background attenuation is much lower than the mean background absorbance found over the spectral range. Similar interferences have been reported for the determination of Bi at 306.8 nm and Mg at 285.2 nm through absorption bands of OH in an air–acetylene flame and also for Fe at 247.3 nm, Pd at 244.8 and 247.6 nm and Yb at 246.4 nm due to PO molecular absorption. Another possible source of error with continuum-source background correction may arise from absorption by concomitant atoms from the matrix. This type of spectral interference has been reported by Manning for the determination of Se in the presence of Fe. Problems with continuum-source background correction in FAAS seldom occur. The background correction system is an extremely useful device for FAAS that frequently leads to the correct results.

However, the continuum-source background correction system is not free from pitfalls. The limited energy of the deuterium lamp lowers the S/N and the correction becomes inaccurate when the background is structured. Most users distrust their results when the background level exceeds 0.5 absorbance unit. The limitations are probably related to the different geometries and possible misalignment of the optical beams of the HCL and the deuterium lamp. The increasing interest in ETAAS as a selective and highly sensitive analytical method has stimulated the development of improved background correction systems.

4 ZEEMAN BACKGROUND CORRECTION

4.1 Zeeman Effect

In 1897, the Dutch physicist Pieter Zeeman(8) reported the observation that if a source of light is placed between the poles of a magnet the lines appear to broaden and, if the magnetic field is strong enough and the resolving power of the spectroscope is sufficiently high, to split into a number of components. The first splitting patterns studied by Zeeman follow from lines of a singlet series. A single line was split into three polarized components.

Both splitting and polarization were explained by Lorentz with the classical electromagnetic theory. A few years later it was demonstrated that the lines of other series do not split into the simple triplet but to a group of four or more components. The classical theory was unable to account for this. Therefore, the two types of splitting were labeled the normal and the anomalous Zeeman effects. An example of the
normal Zeeman effect is presented in Figure 5(a) and Figure 5(b) shows an example of the anomalous Zeeman effect. The splitting pattern is always symmetrical about the position of the nondisplaced line. The components polarized parallel to the magnetic field are referred to as \( \pi \)-components and the components polarized perpendicular to the magnetic field are referred to as \( \sigma \)-components (\( \sigma \) deriving from the German senkrecht). In the case of a normal Zeeman triplet, the \( \pi \)-component is located at the position of the original line at frequency \( \nu \) and two \( \sigma \)-components are found at frequencies \( \nu \pm \Delta \nu \). Such a Zeeman splitting is observed from the direction perpendicular to the magnetic field (transverse Zeeman effect). In the direction of the magnetic field, the central component is not observed whereas the two displaced components are circularly polarized and rotate in opposite directions (longitudinal Zeeman effect). Lines that do not belong to a singlet series split into more than three components. Their pattern is always symmetrical with respect to the position of the original line, with a central group of \( \pi \)-components and groups of \( \sigma \)-components on either side as illustrated in Figure 5(b) for a \( ^2S_{1/2} \rightarrow ^2P_{1/2} \) transition. All Zeeman splitting patterns are observed in both absorption and emission.

The sum of the intensities of the \( \pi \)-components is equal to the sum of the intensities of the \( \sigma \)-components and if the various components are combined, the resulting beam is nonpolarized and the intensity is equal to the intensity observed without the magnetic field. The energy states generated around an original energy level \( E_0 \) are described by Equation (2):

\[
E = E_0 + \mu_B B M_J g
\]

where \( \mu_B \) is the Bohr magneton \( (9.274 \times 10^{-24} \text{ J T}^{-1}) \), \( B \) is the magnetic flux density (tesla), \( M_J \) is the magnetic quantum number and \( g \) is the Landé factor. Both emission and absorption transitions between energy levels are governed by the selection rule \( \Delta M_J = 0, \pm 1 \), where \( \Delta M_J = 0 \) represents the \( \pi \)-components and \( \Delta M_J = \pm 1 \) the \( \sigma \)-components. The displacement of each Zeeman component is proportional to the strength of the magnetic field. In a magnetic field of 1 T the displacement of the \( \pi \)-components in the normal Zeeman effect is 0.467 cm\(^{-1}\), which is equal to 4 pm at a wavelength of 300 nm. The normal Zeeman effect is shown by Be 234.9 nm, Mg 285.2 nm, Ca 422.7 nm, Sr 460.7 nm, Ba 553.6 nm, Cd 228.8 nm and Zn 213.9 nm. Several lines that belong to a triplet series also split into one \( \pi \)-component and two \( \sigma \)-components. However, the shift of their \( \sigma \)-components varies from half to twice the shift in the normal Zeeman effect, e.g. Ge 265.2 nm (1.5), Hg 253.7 nm (1.5), Hg 184.9 nm (1.0), Pb 217.0 nm (0.5), Pb 283.3 nm (1.5), Pd 244.8 nm (1.0), Si 251.6 nm (1.5) and Sn 286.3 nm (1.5). All other transitions used in AAS show anomalous Zeeman splitting patterns that consist of at least two \( \pi \)-components and at least two \( \sigma \)-components. The Zeeman splitting pattern in Figure 5(b) is observed for Ag 328.1 nm, Cu 324.8 nm, Au 242.8 nm, Na 589.0 nm and K 766.5 nm.
Zeeman splitting patterns of the absorption lines used in AAS of various elements were classified in several groups by Koizumi and Yasuda.\cite{koizumi1976spectrochimica} Figure 6 shows the Zeeman splitting patterns for various transitions that are used in AAS.

### 4.2 Principle of Zeeman Background Correction

In AAS, the non- or slightly shifted $\pi$-components are used to measure the total absorbance of the analyte atoms and the background whereas the shift of the (groups of) $\sigma$-components from the original line position is used to measure the background absorbance. Figure 7(a) shows the resonance line emitted by the HCL and the absorption line of the atoms in the graphite furnace at zero magnetic field strength. Note that the width of the absorption line is about twice the width of the lamp emission line owing to the higher temperature and higher pressure in the atomizer compared to the HCL.

**Figure 6** Classification of Zeeman patterns on various elements. $^*$ indicates lines most frequently used in AAS. 1 Å = 10$^{-10}$ m. (Reprinted from H. Koizumi, K. Yasuda, *Spectrochim. Acta, Part B*, 31(10–12), 523–535 (1976), Copyright 1976, with permission from Elsevier Science.)
is switched on and off at high enough frequency, e.g. a 50Hz alternating current (AC) magnetic field, the gross absorbance and the background absorbance can be measured alternately. The net analyte absorbance follows then from Equation (1). The background absorbance $k^b$ is measured exactly at the wavelength of the analyte resonance line $\lambda_a$ and within the width of the HCL emission line profile. Consequently, the background absorbance is measured correctly for any type of background, even if it is highly structured. The alternative approach is to use a constant magnetic field from a permanent magnet or a direct current (DC) magnet and to rotate the polarizer to permit alternate measurements with $\pi$-polarized radiation and $\sigma$-polarized radiation.

Another possibility is to use a longitudinal magnetic field rather than a transverse magnetic field. Figure 7(c) shows that in the direction of the magnetic field only the circularly polarized $\sigma$-components of the analyte absorption line profile $k^{a+}_\sigma$ and $k^{a-}_\sigma$ are observed. In a longitudinal AC modulated magnetic field the gross absorbance is measured at zero-field (see Figure 7a) and the absorbance of the background is measured at exactly the wavelength position of the lamp emission line during the magnet on period. A longitudinal AC Zeeman background correction system does not require a polarizer and therefore the full intensity of the HCL resonance emission line can be used in both measurements.

In all AAS instruments using Zeeman background correction, two alternate intensity measurements are performed. One refers to the unshifted zero-field analyte absorption line (in an AC field) or the slightly shifted and broadened $\pi$-components (in a constant field). The intensity is given by Equation (3):

$$I_1 = I_0^1 \exp(-k^{a+}_\sigma) \exp(-k^{b+}_\sigma)$$

where $I_0^1$ is the incident intensity, $k^{a+}_\sigma$ is the absorption coefficient of the background and $k^{b+}_\sigma$ is the analyte absorption coefficient. The other measurement refers to the situation when the $\sigma$-components are shifted away from the original line position (AC field) or when $\sigma$-polarized radiation is used (constant field). The intensity is given by Equation (4):

$$I_2 = I_0^2 \exp(-k^{a-}_\sigma) \exp(-k^{b-}_\sigma)$$

Figure 7 Profiles of the HCL analyte emission line ($I_{HCL}$) and the absorption coefficient of the analyte ($k^a$) at wavelength $\lambda_a$ in the presence of background absorbance ($k^b$) for the situation of normal Zeeman effect. (a) Conventional AAS, no magnetic field; (b) in the presence of a transverse magnetic field; (c) in the presence of a longitudinal magnetic field.
where \( I_1^0 \) is the incident intensity, \( k_2^b \) is the absorption coefficient of the background and \( k_2^a \) is now the remaining analyte absorption coefficient of the shifted \( \sigma \)-components, which should be close to zero. A simple subtraction of the absorbances measured in both situations corresponds to taking the log ratio of the intensities (Equation 5):

\[
\ln \left( \frac{I_2}{I_1} \right) = \ln \left( \frac{I_2^0}{I_1^0} \right) + (k_1^a - k_2^a) + (k_1^b - k_2^b)
\]

This expression forms the basis for all Zeeman back-

ground correction systems in AAS. When the incident

\[
A = \log \left( \frac{I_2}{I_1} \right) = 0.43(k_1^a - k_2^a) \propto N_A
\]

It is clear that a linear analytical response proportional
to the number of analyte atoms \( N_A \) is obtained. The

source resonance line of about 10 pm is required to allow successive measurements of the gross AAS signal and the background absorbance and propose a system based on magnetic splitting of the source line in a DC or AC magnetic field. The first commercial instrument became available in 1975, incorporating a 1.1 T permanent magnet around the atomizer. The plane of polarization is rotated at 100 Hz to provide for background correction whereas the intensity of the HCL radiation is modulated at 1.5 kHz to eliminate the signal caused by the emission of radiation from the atomizer. Since that time, many other companies have marketed Zeeman AAS instruments. Only a few instruments have the magnetic field around the primary source of radiation. The main reason is that normal HCLs and electrodeless discharge lamps that are widely used in AAS do not fit into the gap of a magnet that has to provide a magnetic field strength close to 1T at reasonable size, power requirements and price of the magnet. In addition, the direction of the discharge in the lamp should be parallel to the direction of the magnetic field to provide a stable beam of radiation. Special lamps have been designed for stable operation in a magnetic field. For nonvolatile elements, instruments were operated with glow discharge lamps in a permanent magnet, whereas low-frequency, high-voltage gas discharge lamps were used for volatile elements.

The more useful alternative is to apply the magnetic field to the atomizer, as discussed in the previous section. Only one manufacturer decided to apply Zeeman background correction to FAAS and therefore constructed a magnet with a gap as long as the conventional 10-cm burner that is routinely used in FAAS. In general, there is no need for Zeeman background correction in FAAS. The continuum-source background correction system works satisfactorily. In graphite furnace AAS, the transverse Zeeman background correction system in Figure 8(a) is marketed by various manufacturers of AAS instruments and most of them use an AC modulated magnetic field of about 0.8 T in combination with a fixed polarizer to reject π-polarized radiation and transmit only σ-polarized radiation. The longitudinal Zeeman background correction system presented in Figure 8(b) was introduced by De Loos-Vollebregt et al. and is also commercially available. In this system, a transverse heated atomizer is placed within a longitudinal magnetic field and there is no polarizer in the optical system. This gives a considerable improvement in light throughput and simplifies the optical system so that detection limits are lower.

4.4 Applications

Zeeman background correction is nowadays widely used in ETAAS. The background correction is performed exactly at the wavelength of the atomic absorption line. High nonspecific absorbances (up to about 2) can be corrected and in the AC Zeeman system sensitivities are similar to those for conventional AAS. Nevertheless, there are a few elements that show somewhat reduced sensitivity because their lines are relatively broad and/or the Zeeman splitting pattern is relatively narrow. An overview of the early applications of Zeeman background correction shows that a wide variety of elements have been measured in different samples and certified reference materials and in the recent years many applications followed. The relatively volatile elements, e.g. Pb and Cd, have been measured by many analytical chemists using ETAAS with Zeeman background correction. This is not surprising because in the determination of volatile elements the pyrolysis temperature is not high enough to remove most of the matrix compounds that are responsible for the background absorption during atomization. Pb and Cd are often determined in a rather difficult matrix such as blood and urine and the low concentrations of the analyte elements do not permit dilution of the samples. The results obtained with Zeeman background correction have been compared with those obtained with continuum-source background correction, looking at the baseline of the net AAS signals. Zeeman background correction seems to be superior, although a fair comparison would require that the same atomizer and atomization conditions are used. There are an increasing number of solid

Figure 8 Schematic diagrams of different Zeeman background correction systems for AAS. (a) Transverse magnetic field, i.e. the magnetic field is perpendicular to the optical axis of the spectrometer. The polarizer provides alternately π- and σ-polarized radiation if the magnetic field is constant or transmits only σ-polarized radiation if an AC modulated magnetic field is applied; (b) longitudinal magnetic field oriented parallel to the optical axis of the spectrometer. No polarizer is required in this configuration.
sampling applications where the Zeeman background correction system is the key to success.

In general, the dynamic range is slightly limited when Zeeman background correction is used. In a strong magnetic field the $\sigma$-components are shifted almost completely away from the absorption line profile so that, according to Equation (6), the shape of the AC Zeeman AAS analytical curve is completely determined by the zero-field absorbance. The analytical curve will therefore be very similar to the corresponding conventional AAS analytical curve measured without background correction. The relatively small contribution of the $\sigma$-components to the measurement of the background has only a minor influence on the slope and the curvature of the AC Zeeman AAS analytical curve. This is equally valid for the normal Zeeman effect and the anomalous Zeeman effect. The same is essentially true when a constant magnetic field is used as long as the spectral line displays a normal Zeeman effect. For the majority of the transitions that show an anomalous Zeeman effect, the splitting in the $\pi$-components broadens the absorption line profile and therefore the linearity of the Zeeman AAS analytical curve is somewhat improved, although the slope is lower.

At very high analyte concentrations, all the ETAAS signals show a dip (see Figure 9) when Zeeman background correction is applied, which can be explained from the phenomenon that is known as roll-over. From the very early days when Zeeman background correction was used, rumors were around that the analytical curve first increases, then reaches the maximum absorption level at relatively high analyte concentration and beyond the maximum decreases again towards the concentration axis. Such a double-valued behavior has indeed been reported for FAAS systems with Zeeman background correction. From a theoretical analysis of the phenomenon\(^{(16)}\), it became clear that the nonabsorbed radiation that is emitted by the primary source and reaches the detector is responsible for this. With increasing analyte concentration, the zero-field absorbance or $\pi$-component absorbance, $k_1^\pi$ in Equation (6), increases much more rapidly than the $\sigma$-component absorbance, $k_2^\sigma$. With increasing analyte concentration, $k_1^\pi$ levels off. The $\sigma$-component absorbance is subject to the same curvature, but at much higher concentration. At a certain concentration a situation is reached where $k_1^\pi$ and $k_2^\sigma$ show the same rate of increase, or equal derivative with respect to concentration. At that concentration, the difference signal according to Equation (6) shows zero slope, i.e. the analytical curve reaches a maximum. Thereafter, a FAAS analytical curve would bend back to the concentration axis. The absorbance and concentration of roll-over are indicated in Figure 9, where the dotted line illustrates the decreasing absorbance values. The height and the position of the maximum depend on the strength of the magnetic field and the amount of nonabsorbed source radiation (so-called stray light). A list of typical roll-over absorbances for ETAAS published by Slavin and Carnrick\(^{(17)}\) is given in Table 2. The characteristic masses are also presented.

Figure 9 shows the net ETAAS analyte absorbance signals. At the lower analyte concentrations, the signals are similar to those in conventional AAS. However, beyond the concentration where the maximum peak absorbance is reached, the signals show a dip. The dip becomes deeper with increasing concentrations. In peak absorbance, the analytical curve levels off when the absorbance of roll-over is reached whereas in integrated absorbance the analytical curve continues to increase but the slope becomes much smaller. It is clear that there is no risk of misunderstanding the measured peak absorbances or integrated absorbances in ETAAS. At high analyte

![Figure 9](image)

concentrations, the signals are analytically useless but there is no double-valued behavior. In FAAS, a warning system for roll-over is used that is based on the detection of the short periods of high absorbance at the start of nebulization and at the end where the atom density is increasing beyond the value that corresponds with the roll-over concentration. Detection of these peaks alerts the analyst that sample dilution is necessary to obtain the correct concentration values.

5 PULSED LAMP BACKGROUND CORRECTION

5.1 Principle

Ling\(^{(18)}\) first advanced the idea of background correction based on the subtraction of absorbances measured alternately with a normal lamp emission line and a broadened lamp emission profile showing a dip in the center. He described a simple method to correct for nonatomic absorption in a portable mercury photometer that included two mercury vapor lamps emitting the mercury resonance line broadened to different extents. Smith and Hieftje\(^{(19)}\) proposed a method for background correction in AAS based on the broadening which occurs in an HCL spectral line when the lamp is operated at very high currents. Under such conditions, the absorbance measured for a narrow atomic line is low, whereas the apparent absorbance caused by a broad-band background contributor remains the same as when the lamp is operated at conventional current levels. Background correction can therefore be effected by taking the difference in absorbances measured with the lamp operated at high and low currents. The so-called Smith–Hieftje background correction system applies its correction very near the atomic line of interest.

5.2 Instrumentation

The HCL power supply and drive circuitry\(^{(19)}\) generate a 9-ms low-current pulse of 5–10 mA, followed by a 0.3-ms high-current pulse of 200–300 mA, as presented in Figure 10(a). The atom cloud in front of the hollow cathode dissipates rapidly for some elements whereas other elements (e.g. Ag, Cd, Cu, Pb) exhibit a persistence of the vapor cloud for more than 6 ms. The total pulse cycle repetition time of 50 ms allows the atomic cloud generated in the HCL during the high-current mode to clear before measurement is made again in the low-current mode for a broad range of elements. Figure 10(b) presents the conventional lamp emission line profile observed at low lamp current and the broadened and self-reversed lamp emission line during the high-current operation of the lamp. It is clear that the narrow line profile emitted under low-current operation is affected equally by atomic absorption or a broad-band spectral feature. In contrast, the broadened and self-reversed profile obtained at high current is affected by a broad-band absorber or scatterer but there is not so much overlap with the atomic absorption line profile. Absorbances calculated under low- and high-current operation are subtracted to yield a difference value which is free of any broad-band contribution.

5.3 Applications

The pulsed lamp background correction method is equally applicable to FAAS, hydride generation AAS and graphite furnace AAS. For effective operation it is necessary to broaden appreciably the emission line of each element under investigation. However, the degree of broadening is different for each element and also depends upon the peak current at which the HCL is driven. To achieve the desired degree of line broadening and line reversal while maintaining HCL reliability and acceptable lifetime, a special design of the lamp modulation circuitry and optimum high lamp current adjustment for each element are required. The slope
of the analytical curves is decreased to some extent when pulsed HCL background correction is applied. The measurement at high lamp current is intended to measure the background. Unfortunately, the broadening of the lamp emission line profile is limited and self-reversal is not complete. The remaining radiation in the central part of the lamp emission line profile is therefore absorbed by analyte atoms and subtracted from the gross absorbance together with the background. For 30 elements most commonly determined by AAS the loss of sensitivity is 47%, ranging from 13% for Cd to 84% for Hg. Similarly to the Zeeman background correction system, the ETAAS signals show a dip at very high analyte concentrations when pulsed HCL background correction is applied. The ability of the pulsed HCL background correction system to overcome background interferences in real samples has been demonstrated. Like the Zeeman approach, the pulsed lamp background correction method requires only a single primary source of radiation and single beam optics so that alignment is simplified.

6 WAVELENGTH-MODULATION CORRECTION METHODS

6.1 Principle

The broad-band spectral distribution of a continuum-source conveniently permits off-line background measurements to be performed in AAS similar to the procedures employed traditionally in atomic emission spectroscopy. Background with a flat spectral distribution requires simply a two-point background correction procedure in which the background absorption at the analytical absorption line is accounted for by a second measurement with the monochromator tuned to an arbitrary off-line wavelength position. The difference between the two measurements provides the net analytical signal. For an absorption line superimposed on a linearly sloping background, two background measurements, one on either side of the absorption line, would be required. The background absorption at the analytical absorption line in this case would be equivalent to the interpolated value of the two off-line measurements. Clearly, with increasing complexity of the background in the immediate vicinity of the analyte absorption line, manual off-line correction procedures would become exceedingly tedious and time-consuming. The use of wavelength-modulation in AAS in conjunction with a continuum primary source of radiation was first described by Snelleman.

6.2 Instrumentation

A vibrating mirror, mounted on the axis of a milliammeter, is positioned in the optical path between the focusing mirror and the exit slit and driven by an AC current which vibrates the mirror at a fixed frequency. The analytical absorption line, when scanned across the exit slit, generates an AC component in the photosignal with a frequency twice that of the mirror vibration frequency. Phase-sensitive signal detection discriminates against DC and first-harmonic AC components of the photosignal due to flat and linearly sloping background distributions, respectively, over the narrow wavelength interval.

Zander et al. combined a high-intensity continuum-source and a wavelength-modulated high-resolution échelle monochromator. A quartz refractor plate modulator was mounted vertically in front of the exit slit. Sinusoidal modulation of the quartz refractor plate scanned the image of the entrance slit rapidly back and forth across the exit slit. In later studies, the refractor plate was positioned immediately behind the entrance slit in order to wavelength modulate the incident nondispersed radiation, permitting wavelength modulation of multiple predetermined wavelengths in the use of a multichannel échelle polychromator. Figure 11 shows a block diagram of a single-channel continuum-source AAS instrument based on a wavelength-modulated high-resolution échelle spectrometer. In this system the exit slit is replaced by a multichannel exit slit unit consisting of 20 prealigned exit slits for different atomic lines and a photomultiplier is positioned behind each slit. Later, more sophisticated detection systems as a linear photodiode array and a segmented array charge-coupled device detector have been used in combination with the échelle optics.

6.3 Applications in Continuum-source Atomic Absorption Spectroscopy

Simultaneous multielement AAS based on wavelength-modulation background correction provides the basic raw data to cover the wide range of concentrations likely to be encountered in different samples because the entire absorption profile can be observed. The intensities at several points across the modulation interval are measured. Using the points at the extreme ends of the modulation interval as \( I_0 \) and those near the center and along the sides of the line as \( I \), several absorbances with different sensitivities are calculated. This set of absorbances is measured and stored for every sample, blank and standard solution. From the set of absorbances measured for a series of standard solutions, a set of calibration graphs with different slopes is obtained. The set of absorbances measured for each sample and blank are converted to concentrations by reference to the corresponding calibration graphs. This procedure yields a set of concentration estimates for each element in each sample. The final concentration estimate is a weighted average based
on the concentration S/N of each individual estimate. The line-center absorbance is utilized at low concentrations and, as the concentration increases, the lower sensitivity absorbances are progressively utilized. The individual calibration graphs are not linear over the entire range. Therefore, a certain number of standard solutions are required to characterize each calibration curve adequately. The wavelength-modulation background correction approach shares with the Zeeman and pulsed lamp methods the advantage of using only a single light source, so that lamp alignment is not so much of a problem as in the continuum-source method, and of making the background measurement at wavelengths very close to the analytical wavelength. Consequently, errors due to background structure and matrix atomic absorption are less likely to occur. The background correction performance of the continuum-source wavelength-modulation method has been evaluated experimentally for a variety of samples.

7 COMPARISON OF METHODS

7.1 Sensitivity and Dynamic Range

From the principle of continuum-source background correction (section 3.1), it is clear that the conventional AAS sensitivity is not influenced by the background correction system. The additional measurement with the deuterium lamp provides the background absorbance and the analyte atoms do not contribute significantly to the background signal because of their narrow absorption line profile.

In all Zeeman background correction systems, the measurement that is intended to provide the background absorbance is slightly influenced by the absorption of the analyte atoms owing to the incomplete shift of the Zeeman $\alpha$-components away from the lamp emission line profile. The contribution of the remaining $\sigma$-components decreases the net analyte absorbance by about 10% for most elements and by up to 45% for a few elements (Cu, Be, Bi). A further decrease in sensitivity is observed in Zeeman background correction systems based on a constant magnetic field from a permanent magnet or a DC magnet for all elements that show anomalous Zeeman splitting patterns. The sensitivity reduction is more severe (about 50%) when a central $\pi$-component is missing. The best Zeeman AAS sensitivity for all elements is obtained in a strong AC magnetic field. The best result in a constant magnetic field of optimum strength is about half the conventional AAS sensitivity, except for those elements that show normal Zeeman splitting patterns.
Pulsed lamp background correction provides sensitivity close to conventional AAS for a few elements only. It is hard to achieve sufficient broadening and self-reversal in the lamp emission line profile during the high-current pulse. Similarly to Zeeman AAS, the contribution of the remaining part of the lamp line profile that is insufficiently shifted is subtracted from the gross absorbance together with the estimated background. The loss of sensitivity varies from 13% for Cd to 84% for Hg.

In wavelength-modulation background correction, analytical curves of different sensitivity are obtained simultaneously. The sensitivity can be selected between the normal value for conventional AAS and much lower values when the analytical information comes from the wings of the line profile. The various calibration graphs become available simultaneously. In comparison with atomic emission spectroscopy, the dynamic range of AAS is limited. Starting from the detection limit, absorbances can be measured over about three orders of magnitude, i.e. from 0.001 up to 1 absorbance unit. This range is not influenced by the continuum-source background correction system. In Zeeman and pulsed lamp background correction systems the dynamic range is further limited owing to the roll-over phenomenon. The analytical curves in peak absorbance level off at somewhat lower absorbances than in conventional AAS whereas the analytical curves in integrated absorbance continue to increase, slowly, up to very high analyte concentrations. In contrast, the wavelength-modulation background correction system offers various analytical curves of different slopes and using them all together the dynamic range is significantly increased in comparison with conventional AAS.

7.2 Frequency of the Background Correction System

All background correction systems involve sequential measurements of the gross absorbance and the background according to Equation (1). In the continuum-source background correction system this requires switching, at a certain frequency, between the HCL and the continuum source. The frequency should be high enough to obtain a good estimate of the background at the time of the measurement of the gross absorbance. In ETAAS, the atomic and background absorption signals may rise to a maximum in times ranging from 0.1 s or less to several seconds, depending on the furnace design, the heating rate and the composition of the sample. The beam switching frequency should be high enough to enable the fastest rates of change of the atomic and background absorption signals to be followed. The upper limit to the chopping frequency follows from practical considerations whereas HCLs can be pulsed at very high frequencies. A high enough background correction frequency of 200–400 Hz can easily be achieved.

In Zeeman background correction systems the frequency is related to the modulation frequency of the AC magnetic field or the frequency of rotating the polarizer in the case of a constant magnetic field. In most of the instruments the background correction frequency is 50–100 Hz. It is complicated to rotate a polarizer at high speed and it is expensive to modulate an AC magnetic field at a frequency higher than the mains frequency. The pulsed lamp background correction system also is not very fast (20 Hz) because the lamp needs time to recover after the high lamp current pulse. In all background correction approaches, an increase in the frequency decreases the time available to measure the signals and consequently decreases the S/N.

Figure 12 shows that for a short interval during the atomization step in ETAAS, each background correction system makes repeated, rapid, sequential measurements of the gross sample absorbance and background absorbance. These measurements are usually spaced evenly in Zeeman background correction and in wavelength-modulation background correction whereas an uneven spacing of the measurements of gross sample absorbance and the background is found in pulsed lamp background correction systems. For accurate
background corrections, the background absorbance must be known at the same time as the gross sample absorbance. Ideally, a mathematical function with the same shape as the background absorbance function would be fit to the background measurements and the background absorbance could be predicted at any time. Various interpolation procedures are used in ETAAS instruments to avoid or reduce background correction errors when the background is changing rapidly.

7.3 Background Correction Performance

The accuracy of the correction for background absorbance must be perfect up to high levels of background absorption. In the absence of analyte, the baseline should be a perfectly straight line even at high background absorbance levels. Three conditions should be fulfilled to accomplish this. In the previous section we have seen that the transient ETAAS signal requires a good approximation of the background at the time of measurement of the gross absorbance signal. In addition, the background must be measured at the same position in the atomizer. This is easily achieved if only one source of radiation is used as in the Zeeman background correction system, the pulsed lamp background correction system and the wavelength-modulation system. In continuum-source background correction, lamp alignment is always difficult because of the different positions of the lamps in the instrument, the different optical paths, the different geometries of the beams and the different intensity distributions. Since the atomic vapor in both the flame and the graphite furnace is not truly homogeneous, nor is the radiant cross-section of either source, perfect matching is difficult. Background absorbance in FAAS is usually low and it can be corrected easily with the continuum-source background correction system.

In ETAAS, the continuum-source background correction system is often also successful. Background correction problems have been observed when the background is higher than about 0.5–1 absorbance unit, often owing to misalignment of the radiation beams. Many instruments are fitted with both a deuterium lamp for the UV and a tungsten lamp for the visible wavelength region. The intensity of the deuterium lamp is quite low when a low spectral band-pass is selected, which may be a limiting factor for the HCL intensity also because most instruments require more or less equal intensities of the two radiation beams.

Continuum-source background correction systems are not able to correct for structured background. The background is measured as an average background absorbance level over the spectral band-pass of the monochromator, i.e. within 0.2–2 nm. Numerous over- and undercorrections have been reported. Several of them are well known and can be found in text books on AAS, others are only observed under very special experimental conditions. Zeeman-, pulsed lamp- and wavelength-modulation-based background correction systems measure the background at exactly the wavelength position of the analyte absorption line or very close to line, i.e. within an interval of 10 pm. Although perfect background correction is not guaranteed, there is a better chance that the right background absorbance is measured at a wavelength position close to the absorption line in comparison with the average value over the full spectral band-pass. The Zeeman background correction system that applies the magnetic field to the atomizer is the only system that provides correction for the background exactly at the wavelength of the analyte absorption line. Even here, perfect background correction is not guaranteed because, in a very few cases, the background may change with the strength of the magnetic field in AC Zeeman systems. Most of the background correction errors reported for continuum-source background correction are not found when Zeeman, pulsed lamp or wavelength-modulation background correction is applied.

8 BACKGROUND CORRECTION PROBLEMS AND HOW TO AVOID THEM

The most frequent spectral interference in continuum-source background correction results from atomic absorption of the background radiation by massive amounts of metals in the matrix, usually at secondary absorption lines of these elements. However, some of the structured absorption errors result from molecular absorption in the vapor phase. Probably the first identified example of background correction error was the influence of large amounts of Fe in the determination of Se at the 196-nm line. A list of potential interferences of this type shows errors that may occur, based on the wavelengths of the various lines. Some of the problems are very unlikely to be serious in FAAS. In the graphite furnace the amount of matrix is typically much larger relative to the analyte and therefore interferences can be more severe. However, during method development much time and effort are usually spent in obtaining an acceptable program for heating of the graphite furnace and the application of chemical modifiers is also considered. Owing to the improved graphite furnace design, the temperature program used and the application of chemical modifiers, potential interferences and background correction errors are not always found in real analysis.

Background correction errors are hard to identify when the background absorbance takes place simultaneously.
with the atomic absorption. If there is some time delay between the two processes, a positive or negative disruption of the baseline may be observed just before the atomic absorption starts or just after the atomic absorption is finished. It should be noted that the method of standard additions does not control background correction errors.

Several problems of background overcorrection have been noted that have not yet been fully explained whereas others are well understood. For example, the effect of phosphate on Se and As is related to molecular P_2 that is generated in the vapor phase of the furnace and the molecular band absorbs the continuum radiation.

With Zeeman background correction, the pulsed lamp background correction system or wavelength-modulation, most of the interferences reported for continuum-source background correction are not observed. Nevertheless, a few interferences have been reported. In most of the commercial Zeeman instruments, background correction is achieved by using an AC magnetic field transverse to the optical axis. If matrix absorption lines or molecular bands that are very close to the analyte wavelength exhibit Zeeman splitting, correction errors may occur. A matrix absorption line that does not overlap with the lamp emission line at zero-field may do so at maximum field strength, or the other way around. An example of such problems is the PO molecular absorption band that causes an overcorrection for lead in the presence of phosphate. The overcorrection error is influenced by the strength of the magnetic field. It is diminished by decreasing the amount of phosphate or by replacing the standard transverse-heated graphite atomizer with an end-capped tube. Accurate results for the determination of Pb in bone show that such background correction errors can be avoided by optimization of the experimental conditions during method development.

**REFERENCES**

Atomic absorption spectrometry (AAS) is a means of specific analysis for most of the metallic and metalloid elements. It achieves its specificity from the highly selective absorption, by free atoms of the analyte, of atomic emission of the same element at characteristic wavelengths. In its simplest form of application the free atoms of the analyte are created by aspiration of a solution of the sample to be analysed into a suitable flame, flame atomic absorption spectrometry (FAAS). The other principal means employed for the production of atoms (atomization) are graphite furnace atomization (GFAAS) and vapor generation atomization (VGAAS). Sample volumes of a few milliliters are normally needed for FAAS and VGAAS, but smaller volumes are needed for GFAAS. For most of the approximately 65 elements amenable to measurement by AAS, detection limits are from parts per billion to parts per million by flame methods and from parts per trillion to parts per billion levels by GFAAS and VGAAS. FAAS is inherently simple and rapid to use, whereas GFAAS and VGAAS are less rapid. The instrumentation used for AAS is relatively inexpensive. Since all of these methods generally require the sample to be in solution form, the need for dissolution may be seen as a limitation in some cases. In the most common instrumentation employed, elements are only measured one at a time. It follows that for the determination of many elements in a large group of samples the method must be seen...
to be slow by comparison with multielement techniques such as inductively coupled plasma mass spectrometry (ICPMS) and inductively coupled plasma atomic emission spectrometry (ICP-AES). However, the equipment costs involved for these techniques are generally higher and they are more complex to employ.

1 INTRODUCTION

1.1 The Origins of Atomic Spectra

Although astronomical observations led to the discovery of the ‘Fraunhofer (atomic absorption) lines’ in the solar spectrum, it was not until about 1850 that the origin of these dark lines in an otherwise continuous bright spectrum started to be properly deduced. It appears that several workers, among them Foucault, Balfour Stewart and Stokes started to realize that these lines were the result of absorption of the continuous emission from the sun and other astronomical bodies by the atomic vapor of some elements occurring in their atmospheres. It was not until 1860 that Bunsen and Kirchhoff first comprehensively demonstrated experimentally, and then elucidated, the origin of such atomic emission and absorption spectra and drew attention to their interrelationship.

In what are now seen as classical experiments they demonstrated that atomic vapors of sodium and lithium, produced in a flame, would each not only emit radiation at specific wavelengths but would also absorb radiation at precisely the same wavelengths.\(^1\)\(^2\) Kirchhoff’s original paper\(^1\) is given only for completeness but the paper, and of course the title, are in German. However an English translation of this paper is also available.\(^2\) From these results Kirchhoff elucidated that atomic transitions between different energy levels might be observed either using absorption or emission.

He found that if, for example, a solution of a sodium salt was heated in a flame it would then spontaneously emit or absorb radiation at wavelengths characteristic for sodium only; the famous ‘D lines’. Likewise a solution of a lithium salt would also, under the same circumstances, emit or absorb radiation at a wavelength different from those of sodium but equally characteristic for lithium only. By doing this he essentially drew attention to the potential usefulness of such observations to identify the presence or absence of sodium and lithium (qualitative analysis). This work was later extended, by Bunsen and Kirchhoff, to the qualitative determination of the presence of other elements (potassium, calcium, strontium and barium).\(^3\)

As an interesting example of the powerful usefulness of atomic spectra, these workers also first discovered the existence of the elements rubidium and cesium by observing the presence of other characteristic (and unexpected) lines when employing solutions of natural salt for their experiments.\(^4\) The salt they used was not produced from the evaporation of seawater but rather was natural salt from underground deposits.

(Note that the Kirchhoff articles\(^5\)\(^4\) are also translations of articles originally published in Annalen der Physik und Chemie.)

Bunsen and Kirchhoff only employed these observations in a qualitative mode and seem to have drawn no attention to the possible quantitative use of the phenomena of atomic emission and absorption.

This does not seem too surprising given that in 1860 means of quantitative measurement of emission or absorption signals were not readily available.

1.2 First Analytical Applications of Atomic Spectra

Later, starting with the further development of the photographic process, the means of recording intensities for at least semiquantitative purposes was to lead to the development of emission spectrography using (initially) electric arcs as the means of excitation.

Flames were also seen to be a potential means of excitation for observing emission and by 1928 Lundegardh developed suitable burners (using acetylene as the fuel gas and air as the support gas) and methods for sample introduction.\(^5\) From this time on, and for the period to the 1950s, developments continued in the above methods but the use of methods utilizing atomic absorption spectra were almost totally ignored. As will be described in section 2, this was in major part because the means of measuring atomic absorption with good sensitivity was not yet properly developed.

1.3 Suggestions for the Analytical Use of Atomic Absorption Spectra

After a significant period of research into atomic emission spectrometry (AES), Walsh became convinced that this neglect of the use of atomic absorption had gone on for too long. He recognized that there would be potential advantages in using the measurement of atomic absorption instead of atomic emission as a means of measuring the concentration of elements in samples.

The major advantages he postulated for the use of atomic absorption methods were as follows:

- Since ground-state atoms would be used for the measurement, the method should be independent of the excitation potential of the element to be measured.
- The method should be much less influenced by the temperature of the atomizing device used.
• There should be much less likelihood of spectral interferences impairing the accuracy of the method.

In 1955, Walsh published a landmark paper explaining, in major detail, these theories. Additionally, however, he also defined a practical approach to the necessary key elements required for instrumentation to measure atomic absorption.\(^{(6)}\)

Completely independently, Alkemade and Milatz also published an article suggesting the use of atomic absorption spectra.\(^{(7)}\) They, however, did not develop the practical means of performing this measurement to the same extent as Walsh and this limited the importance of their paper in a practical sense.

In the following section, the theoretical basis of atomic absorption and its measurement will be dealt with in more detail.

## 2 THEORETICAL BASIS OF ATOMIC ABSORPTION SPECTROMETRY

### 2.1 General Comments

At this juncture, any comparisons made will be solely between flame emission and flame atomic absorption and no further reference will be made to emission measurements made following excitation by electric arc or spark or by inductively coupled plasma. These are all established methods in widespread use, although arc and spark spectrometry is currently in much less use than in previous years.

In order to measure atomic absorption, it is first necessary to produce free atoms of the element to be measured. However, it should be realized that it is also necessary to produce free atoms of any element to be measured by atomic emission. Atoms cannot be excited unless they are first converted to free atoms from any compound associations.

### 2.2 Atomization and Excitation

In most atomic absorption, or flame emission, methods atoms are produced from a sample in solution form by the application of heat. If a solution sample is introduced, for instance, into a flame then atomization will often occur. Depending on the excitation potential of the element in question, some of these atoms produced may also then be excited. It is this atomization, and subsequent excitation, which forms the basis of flame emission spectrometry. However, as Walsh pointed out, there are some important factors which should be considered. These are best expressed in some figures taken from a table in his first paper, shown here in Table 1.

\(^{(a)} N_j\) is the number of atoms in the excited state at any given time and \(N_0\) is the number of atoms in the ground (unexcited) state at any given time, and consequently the ratio \(N_j/N_0\) is the fraction of atoms in the excited state at any given time. The figures quoted are taken from a table which appears in Walsh.\(^{(6)}\) They represent only some of the entries in that table and have been rounded off for convenience.

The figures in Table 1 show that

- the fraction of excited atoms at any time is always a very small fraction of the total atoms present;
- the fraction of excited atoms changes by a huge amount with any major temperature change;
- since the fraction of ground-state atoms is equal to one minus the fraction of excited atoms, this remains sensibly constant at very close to 1, regardless of temperature change.

Since atomic emission signals originate from excited atoms and atomic absorption signals from ground-state atoms, the consequences of the above are the following:

- Atomic emission signals will be dramatically affected by temperature changes but absorption signals will be affected to a much lesser extent.
- For many harder to excite elements (such as Zn in Table 1), atomic absorption will be much more sensitive than atomic emission at such temperatures.
- All excited states will, at any given time, have a very small population of atoms. As a result, sensibly only those transitions which originate in the ground state will be able to be measured by atomic absorption. It follows, then, that since there are only a very limited number of such transitions for each element, the atomic absorption spectrum of all elements will be very much simpler than the atomic emission spectrum of the same element. The major consequence of this is that the likelihood of spectral interference will be much lower for absorption measurements than for emission measurements.

Properly, the resonance line for any element is the line associated with the transition between the ground state and the first (lowest energy) excited state. There is therefore commonly only one true resonance line per element. In the years since atomic absorption analysis was
introduced, the convention has arisen that all lines which are associated with transitions involving the ground state are called resonance lines. This atomic absorption convention will generally be followed throughout this article.

2.3 Absorption and Emission Lines

A purely diagrammatic representation of the energy levels involved in the production of an emission and absorption line is shown in Figure 1.

The relationship between the difference of the two energy levels involved in the transition and the frequency of the radiation emitted or absorbed is given by Equation (1):

\[ E_1 - E_0 = h\nu \] (1)

where \( E_1 \) and \( E_0 \) are the two energy states, \( h \) is Planck’s constant and \( \nu \) is the frequency of the radiation emitted or absorbed. In spectroscopy in the ultraviolet and visible regions of the spectrum wavelengths are more commonly used rather than frequency, so Equation (1) may be rewritten as Equation (2):

\[ E_1 - E_0 = \frac{hc}{\lambda} \] (2)

where \( c \) is the velocity of light and \( \lambda \) is the wavelength of emission or absorption. Rearranging, we obtain Equation (3):

\[ \lambda = \frac{hc}{E_1 - E_0} \] (3)

Since \( h \) and \( c \) are both constants, it follows that the wavelength corresponding to the change of energy of the atom, from one energy level to another, is inversely proportional to the difference between the two energy levels. Since the same two energy levels are involved, it follows that the emission and the absorption wavelengths will be identical since the calculation is the same in both cases.

2.4 The Shape of Spectral Lines

The emission and absorption wavelengths are generally quoted in texts as being, for example, Cu 324.754 nm, and it might often be assumed that this means a line of virtually no shape, i.e. an infinitely narrow line. Such is not the case, however, and lines do have a finite width and shape, both of which will vary under certain conditions. The wavelength designated might be seen as the central wavelength, but there will be present under all conditions a distribution of wavelengths around that central wavelength (called the ‘natural’ line width). Various factors may increase the line width further (‘broaden’ the line).

In a short survey such as this article, only the two principle causes of line broadening will be considered. The first of these is Doppler broadening, caused by the fact that in a vapor cloud the atoms will be moving in all directions. Observations of emission from an atom coming towards the point of observation at the time of emission will record a wavelength shorter than that recorded from an atom going away from the point of observation at the time it emits. Obviously, as the temperature is increased the velocity of motion of the atoms is increased and this effect will therefore increase with increasing temperature, producing an increased line width.

The second cause is pressure broadening due to the concentration of atoms and molecules in the vapor in which the emission is occurring. The higher these concentrations are, the greater is the broadening which will occur.

The combined effects of these two (and some other minor) causes of broadening is to produce an emission line with an approximately Gaussian profile, as shown in Figure 2(a). The usual manner of describing the width of this line is the ‘half-width’, that is, the width at half the maximum peak intensity. The use of this manner of describing line width is necessary because the maximum width which exists, as zero intensity is approached, becomes progressively harder to measure and is dependent on the sensitivity of measurement available and the concentration of the atoms responsible for the absorption or emission.

Under the conditions prevailing in a flame, burning at atmospheric pressure at a temperature in the 2000–3000 K range, the half-width of the absorption lines will be of the order of 0.002–0.01 nm. An absorption line may be drawn, as shown in Figure 2(b), following the convention of drawing absorption lines downwards and emission lines upwards. For the understanding of this diagram, and for descriptions which will follow later, it is necessary to describe just what it illustrates, as far as atomic absorption measurement is concerned.

For any absorption spectrometric method, the absorption signal is always designated in terms of “absorbance” (A) and this is defined as \( \log_{10}(I_0/I) \) where \( I_0 \) is the intensity of the original source radiation and
2.5 Measuring Atomic Absorption

2.5.1 Using Continuum Source Emission

Early concepts of measuring atomic absorption were based on the idea of measuring the absorption of light from a continuum source, but this approach has limited value for the following reason. The spectral band-pass of a monochromator of modest resolution, say 0.2 nm, can be represented as shown in Figure 3 with a representation of an absorption line with a half-width of approximately 0.01 nm superimposed on it. It can be seen that the sensitivity of this measurement will be limited, since even if the peak absorption at the center of the absorption line is, for example, 40%, perhaps less than 1% of the total energy reaching the detector will be absorbed. In addition, it is obvious that changes of absorption with concentration of the atoms of the analyte will give rise to a nonlinear function.

Naturally, the sensitivity may be improved by using a higher resolution monochromator as represented, for example, as 0.05 nm in Figure 3. However, the absorption will still probably be less than 2–3% of the total radiation. Also, and equally important, with such a narrow slit opening, the total intensity of radiation from a typical continuum source would be very low and the precision of the measurement function would therefore be limited by this low intensity.

2.5.2 Using a Sharp Line Emission Source

One of Walsh’s major contributions to the subject was to suggest that peak absorption could be measured if use was made of a line source, providing emission at precisely...
the same wavelength as the absorption, and having a line width much less than that of the absorption line. This situation is represented in Figure 4.

The means of providing such a sharp line emission, at precisely the same wavelength as the absorption, was to use an individual hollow-cathode lamp (HCL) to provide the emission spectrum for each element to be determined. The construction and operation of such lamps will be discussed more in the next section, but at this stage it is useful to indicate why this sharp line emission occurs.

An HCL operates at reduced pressure, typically 1–2 kPa, so the concentration of atoms and molecules within the tube will be much less than in a flame at atmospheric pressure and this will reduce pressure broadening. Additionally, the temperature of the discharge will be only perhaps 500–600 K, compared with flame temperatures of 2000 K or more, and this will reduce Doppler broadening. Under these conditions, a HCL produces emission lines with half-widths of the order of 0.0004–0.002 nm.

As shown in Figure 4, it should be understood that the major part of the emission signal will be capable of absorption at or near the center of the absorption line, that is, at the wavelength where the absorption coefficient is at its maximum. This will result in maximum sensitivity of measurement. Quantitatively, the amount of energy at the maximum and minimum wavelengths of the emission line (the left- and right-hand flanks of the line as shown) will be very small. As a result, the fact that at these wavelengths the absorption coefficient will be slightly smaller will have only a small effect on the overall sensitivity achieved.

2.6 Spectral Interferences in Atomic Absorption Spectrometry

True spectral interferences may be defined as spectral interferences which, if undetected and uncontrolled, may lead to an error in the results obtained. There is another phenomenon, here termed “pseudo-spectral interference”, which can affect measurements and this will be described first. It is not really a spectral interference since it only contributes to the quality of the measurement function and does not cause incorrect results. This minor problem will be dealt with first.

2.6.1 Pseudo-spectral Interferences

As illustrated in Figure 4, it may be seen that the emitted line from the light source used to make the measurement may be absorbed by the atomic absorption process, the amount of absorption being dependent on the concentration of the analyte present. If for whatever reason there is an emission produced by the light source which results in a line within the spectral band-pass of the monochromator, but which is not overlapped by the absorption line, as shown in Figure 5, no interference will be produced.

However, since the extraneous line will not be absorbed, regardless of how great the concentration of the analyte is, some loss of sensitivity of the measurement will occur and the calibration function will be nonlinear. Two means are available which may successfully overcome this problem:

- employ a narrower spectral band-pass from the monochromator by altering the slit opening;
- remove the element which gives rise to the extraneous line.
With regard to the first of these solutions, it should be recognized that in Figure 5 the spectral band-pass is roughly 0.04 nm (if we assume that the half-width of the absorption line is about 0.01 nm). To eliminate the effect of the “interfering” line the slit opening would need to be closed to a spectral band-pass of about 0.02 nm and this would require a relatively high resolution monochromator.

The second solution will be possible, for example, if the foreign line is due to the fill gas of the HCL by replacing it with a different fill gas. If the foreign line is due to an element other than the analyte, and which is introduced in the construction of the cathode, then the construction of the cathode might be modified to remove this element.

Should the foreign line be a nonresonance line of the analyte itself, then the second solution is not possible and only the first solution can be used either to remove or at least to minimize this curvature of calibration. It must be emphasized again, however, that curvature of calibration is only a minor operational problem and does not in itself cause errors in the analysis.

2.6.2 True Spectral Interferences

By comparison, again with Figure 4, if another element has an absorption line within the spectral band-pass of the monochromator, as illustrated in Figure 6, then no interference will occur. This is because there is no overlap of the other absorption line with the emission from the sharp line source at the resonance wavelength.

Should there be, however, a much closer absorption line, such as shown in Figure 7, then interference is possible since the left-hand flank of the absorption line of B does, as represented here, slightly overlap the right-hand flank of the emission line of the analyte (A).

It should be appreciated, however, that, in addition to the separation of absorption lines, the relative concentrations of the two elements A and B will affect this situation. In the absorption line for element B, at low concentration (shown as the full line) there is a small overlap but as represented it would cause only a slight absorption of a very small part of the total emission signal. However, the absorption due to a higher concentration (represented by the dotted line) is at a greater absorption coefficient, and the overlap is greater. This means that the potential interference will be more significant. Note that the absorption line, as represented, is actually effectively wider. This is because the concentration of atoms absorbing at these flank wavelengths is greater and so the effect will be more observable. Remembering that \( a = k c \), this may be seen as the effect that even though \( k \) may be very low as zero absorption coefficient is approached, the effect of multiplying a low \( k \) by a high \( c \) will result in a larger signal.

Nothing can be done about this type of interference except to use a different resonance line of A for the measurement, since clearly limiting the spectral band-pass of the monochromator will not remove the problem.

When the method was first proposed, it was suggested that since the total atomic absorption spectra of all elements were relatively simple, such interferences might be expected to be rare. This has proven to be the case and no more than 10–12 such interferences have been reported, often rather exotic and unlikely to be encountered in practice. For example, such an interference does occur between copper and europium, as illustrated in Figure 8. The most sensitive line of copper at
324.754 nm is very close to an absorption line of europium at 324.753 nm. Referring to Figure 8, if we assume that the half-width of the emission line is 0.0002 nm, then the separation of the central wavelengths of the two absorption lines shown is about 0.001 nm. As may be seen, the copper emission line from the HCL is slightly overlapped by the tail of the europium absorption line. This line is not the most sensitive line for europium so its absorption coefficient would be very low, and additionally the overlap is very small.

In fact, significant interference will only be observed if the Eu–Cu ratio is greater than about 500:1. However, if copper needed to be determined, in a sample which contained a very high concentration of europium an error would occur. In what is, after all, a rare analytical situation, the solution to the problem would be to measure copper at the alternative resonance wavelength of 327.4 nm where no such interference occurs and where the sensitivity for copper measurement is reduced by a factor of only about two.

Another case of true spectral interference is the possible absorption of the resonance line of the analyte by molecular absorption. Some molecular species, which might be produced in the atomizer from certain sample types, might have absorption bands which overly the resonance wavelength. Such nonspecific absorption can occur in the presence of high salt concentrations, particularly at wavelengths in the low-ultraviolet region of the spectrum (below 300 nm).

This type of interference is seldom very major in flame atomization but may be needed for the most precise analyses, particularly for measurements at very short wavelengths. It is, however, very important in furnace atomization methods and for this reason background correctors have been developed and will be discussed briefly in the next section.

3 INSTRUMENTATION FOR ATOMIC ABSORPTION SPECTROMETRY

Following the publication of his first paper, Walsh, with some colleagues, described a suitable instrument for the practical measurement of atomic absorption spectra.

The essential component sections of an atomic absorption spectrometer are shown in Figure 9. As illustrated these are as follows:

- a light source (usually an HCL) which provides a sharp line emission at the resonance wavelength for the element to be measured (analyte);
• an atomizer (shown here as a flame) which produces free atoms of the analyte;
• a wavelength selection device (usually a monochromator) which allows the isolation of this resonance line from other lines produced in the spectrum of the lamp;
• a detector (usually a photomultiplier tube) which measures the intensity of the signal which is passed by the wavelength selection device;
• an amplifier–read-out device which processes the signal from the photomultiplier and converts it into a suitable form from which the result is obtained.

Each of these component sections will now be examined in some detail.

3.1 Light Sources

3.1.1 Hollow-cathode Lamp

The principal light sources which were first used in the development of a practical atomic absorption instrument, in the early 1950s, were HCLs. Such lamps were, at the time, relatively uncommon and an initial task of Walsh and his colleagues was to perfect the means of making such lamps which were both stable and exhibited adequately long lives. Possibly surprisingly, nearly 50 years later, such lamps still remain the basis of most atomic absorption instruments. A sketch of such a lamp and an illustration of its operation appear in Figure 10(a) and (b), respectively.

The lamp consists of a glass envelope into which are sealed the contacts leading to the anode and cathode. The cathode is either made from the element whose spectrum is sought, an alloy containing this element, or a compacted powder mixture of the element or a compacted powder mixture containing the element.

A fused-silica window is sealed to the end of the lamp with a ‘graded seal’ joining the window to the envelope. This is necessary as the coefficient of expansion of the glass in the envelope is much greater than that of the silica and cracking would result following the heating and cooling which take place during lamp operation.

The lamp is filled with a monatomic inert gas such as argon, helium or neon, at a low pressure (1–2 kPa). Early lamps generally used argon as the fill gas but for some time neon has been used as the ‘standard’ fill gas. Argon is used for a few lamps, principally for lamps of elements where the presence of neon causes the emission of lines which are closely adjacent to the resonance lines commonly used for the measurement of that element. In operation, a potential difference of 400–500 V is applied between the anode and the cathode. Initially this ionizes some of the neon (or argon) and once current flow commences the potential difference across the electrodes will fall to about 250 V. The positively charged ions of the inert gas are attracted to the (negatively charged) cathode by electrostatic forces, causing the ions to be rapidly accelerated towards the cathode.

The rapidly moving ions of the inert gas, on striking the interior of the cathode, dislodge atoms from the cathode material (“cathodic sputtering”), creating a cloud of atoms at the mouth of the cathode. Many of these atoms are excited by collision with more of the rapidly moving ions of the inert gas and then, on spontaneously returning to the ground state, emit the emission spectrum of the element.

The total spectrum produced by this process will consist of atomic and ionic emission lines of the inert gas and atomic and ionic emission lines of the element(s) contained in the cathode. Of course, for any element the strongest atomic emission lines will be the resonance lines, since the resonance transitions will be the most likely to occur.

Such HCLs can be made for all of the elements which may be determined by atomic absorption, and are the standard light sources used for most analytical atomic absorption measurements. They do, however, have finite lifetimes due to a process which is called “clean-up”.

As described earlier, HCLs operate by some of the material of the cathode being removed, as atoms, by a sputtering process. After these atoms have been excited and given off their emission signals, they eventually condense on a cooler part of the lamp as a thin film of the metal. In general, most of this thin film of metal appears on the portion of the inner wall of the lamp which is immediately adjacent to the cathode itself as a mirror like layer. Since this film is literally deposited atom by atom, it has a very large surface area and adsorbs...
some small amount of the fill gas used in the lamp. Eventually this adsorption process reduces the fill gas pressure sufficiently that the lamp will no longer sustain a hollow-cathode discharge and the signal of the resonance line is no longer strongly produced. At this stage the lamp must be replaced.

Operating lifetimes of lamps were initially a problem, particularly for some volatile elements, but, with progressive development, today are typically from 1000 to as much as 10,000 h or longer.

Light sources other than HCLs have been used through the period of development of the technique but only two of these are commercially available and in serious use today. These are the boosted discharge HCL (initially called the “high-intensity lamp”) and the so-called electrodeless discharge lamp.

3.1.2 Boosted-discharge Hollow-cathode Lamp

This has the essential construction of an HCL, but with additional auxiliary electrode(s) sealed into the lamp beside the open end of the hollow cathode, as shown in Figure 11. Similar designs have been used by various manufacturers, variously called “high-intensity lamps” and “super lamps”, but the principle remains essentially the same.

For probability reasons, such as described earlier for flame excitation, most of the atoms in a hollow-cathode discharge are in the ground state at any given time. Many of these atoms may be excited by the passage of a low-voltage discharge from the auxiliary electrode(s) through the atom cloud which exists in front of the cathode. The result is a more intense emission signal and, because the auxiliary discharge is of low energy (voltage), a greater proportion of the extra emission signal occurs at the resonance lines.

3.1.3 Electrodeless Discharge Lamps

A typical commercially available electrodeless discharge lamp is illustrated in Figure 12.

An electrodeless discharge lamp consists of a small, sealed-off silica bulb containing a very small mass of the element whose emission spectrum is required and a low pressure of inert fill gas. Excitation is by a radiofrequency signal coupled into the contents of the bulb via an induction coil surrounding the bulb. Such lamps are only readily produced for relatively volatile elements such as As, Se, Na and K, but for these elements more intense signals are produced compared with HCLs. Additionally, since HCLs for these volatile elements have shorter lifetimes, as described above, the electrodeless discharge lamps often also have the advantage of longer operating lifetimes.

3.1.4 Operation of Light Sources

Since the most sensitive wavelengths for atomic absorption are generally also the most sensitive wavelengths for atomic emission, some interferences may occur for elements which are significantly excited in the flame atomizer. This is because the flame atomic emission signal would add to the total signal incident on the detector. To overcome this, the signal from the light source is modulated, and an alternating current (AC) amplifier is then able to discriminate this signal from the (essentially) direct current (DC) signal produced by flame atomic emission. Such a modulated signal may be produced by applying a modulated current to the light source or by

![Figure 11 A boosted discharge HCL. (Reproduced by permission of Photron Pty Ltd. from Photron Lamps.)](image1)

![Figure 12 An electrodeless discharge lamp. (Reproduced by permission of Perkin-Elmer Corporation from Concepts, Instrumentation and Techniques in Atomic Absorption Spectrophotometry, 1978.)](image2)
mechanical chopping. Both techniques are in use in commercial instruments, as will be shown later in this section. A stable power supply is necessary, regardless of which of these modulation procedures are used, in order to produce a stable output from the light source.

3.2 Atomizers for Atomic Absorption Spectrometry

Without the production of free atoms, atomic absorption cannot be measured. It is in this section of the instrumentation that the operator of an atomic absorption spectrometer has the most control over the actual analysis and its veracity. Since the choice of the means of atomization employed and its detailed operation are of such fundamental importance to the technique, more detailed discussion will be postponed until later.

3.3 Wavelength Selection

As has already been discussed, the real resolution of atomic absorption measurement is provided by the absorption process itself. The function of the monochromator in the technique is therefore only to ‘tidy up’ the emission spectra from the light source. This is illustrated diagrammatically in Figure 13.

Here it may be seen that the light source is producing a spectrum, in the vicinity of the desired resonance wavelength \( R \), containing a number of other lines. These lines may consist of other lines of the analyte, lines produced by other elements in the cathode material and lines of the fill gas of the lamp. Separating the resonance line (\( R \)) from all other lines in the vicinity is desirable in order to maximize sensitivity and limit calibration curvature.

Generally a modest monochromator will achieve this fairly readily, with a spectral band-pass of 0.7–1 nm usually being adequate. In a few cases where the analyte itself has another line near the resonance line (and this occurs with Fe, Co and Ni), a spectral band-pass of 0.2 nm will be advantageous in the interests of achieving a calibration graph which is as linear as possible.

Initially monochromators which employed prisms for dispersion were commonly employed. However, for several years now most atomic absorption spectrometers have employed a monochromator with a diffraction grating as the means of wavelength dispersion. Such monochromators are more desirable than those employing prisms for dispersion as the wavelength settings are less prone to drift with temperature change. Obviously this is an important property when hot flames are being used as the means of atomization.

3.4 Detectors

The universal detectors of atomic absorption spectrometers for many years have been photomultiplier tubes. In the formative years of the technique it was often considered necessary, for the best results, to employ two different types. The range of AAS, as normally used, is from 193.7 nm for arsenic to 852 nm for cesium. In the 1950s there were no photomultipliers that covered this entire range with good sensitivity. Users who wished to measure arsenic and selenium as well as potassium needed two different types (rubidium and cesium, if needed, made this situation even more acute, but very few analysts measured these elements).

Two factors have altered this situation since that time. First, more intense light sources, including electrodeless discharge lamps, made the problem less acute. Second, the technology of photomultiplier tubes has improved and much better tubes with a wider wavelength range have been developed. Both of these improvements, of course, had a compound effect and today a single photomultiplier tube is all that is needed.

3.5 Amplifier and Read-out

As indicated before, the amplifier should respond only to a modulated AC signal and ignore any essentially DC signal resulting from flame emission. For the best performance this is accomplished by employing an amplifier tuned as closely as possible to the frequency at which the light source signal is modulated. Preferably it should be a synchronously demodulated amplifier which is “locked into” to the frequency of the lamp modulation.

The relationship between the concentration of the analyte and its absorption is logarithmic so that the amplifier will incorporate a logarithmic function to achieve a linear, or close to linear, read-out. Modern amplifier systems also incorporate mathematical and curve fitting functions to achieve direct concentration read-out of the result, regardless of whether the calibration function is linear or otherwise.

![Figure 13 Isolation of a resonance line.](image-url)
4 ATOMIZATION SYSTEMS AND THEIR USE

4.1 Historical
Historically the first actual use of atomic absorption measurements for quantitative analysis occurred in the late 1930s, long before Walsh’s first suggestions. The British company Adam Hilger (later Hilger and Watts) developed an instrument to measure the concentration of mercury in air samples. This was a specialized approach to serve a particular need and was, of necessity confined to mercury. Of all the elements which may be measured by AAS, mercury is the only one which can exist at room temperature and pressure in the stable form of free atoms. Later discussions will concentrate on mercury individually but, for the moment, more general approaches need to be considered.

4.2 Flame Atomization

4.2.1 Early History of Flame Atomic Emission
Flame atomization methods had been in use for many years when atomic absorption methods started to be developed in the 1950s. They had been used in flame emission analysis since the beginning of the century although probably seriously only after the important work of Lundegardh in 1928. This was a specialized approach to serve a particular need and was, of necessity confined to mercury. Of all the elements which may be measured by AAS, mercury is the only one which can exist at room temperature and pressure in the stable form of free atoms. Later discussions will concentrate on mercury individually but, for the moment, more general approaches need to be considered.

4.2.2 Initial Developments of Flame Atomizers of Atomic Absorption
When investigations into the use of atomic absorption spectra for chemical analysis first commenced, the emphasis was initially on those elements which, although easy to atomize, were difficult to excite. These include Zn (213.8 nm), Cd (228.8 nm), Ni (232.0 nm) and Pb (283.3 nm). Because of the short wavelengths associated with these resonance lines, the energy required to excite the atoms is relatively high.

Initial use was made of burner systems from existing (emission) flame photometers which employed premix systems and employed relatively cold flames such as air–coal gas (ca. 2100 K). It was immediately found that it was possible to measure elements such as Zn and Cd with excellent sensitivity, comparable, for example, to the sensitivity obtainable for Na and K. This immediately proved one of the major benefits, initially claimed for atomic absorption, that it would be independent of the excitation energy required to populate the first excited state. It was also realized that since the method did measure absorption, a longer absorption path length increased the sensitivity, and suitable elongated slot burners were soon developed. Such burners had to employ slot dimensions which were matched, as closely as possible, to the geometry of the beam of light from the HCL.

4.2.3 The Use of the Air–Acetylene Flame
It was soon realized that although high energy was not needed for excitation purposes, it was, for some elements, needed to achieve atomization. The development of elongated slot burners suitable for use with the air–acetylene flame (in the early 1960s) extended the technique to a number of additional elements so that by this period about 35 elements could be determined by AAS using this flame. (The scientist most instrumental in the first development of air–acetylene burners, suitable for atomic absorption, was Allan.)

Relatively soon this flame became virtually the standard flame in use and this remains the situation today. Several of the additional elements, however, either had modest sensitivities or suffered from a number of matrix interferences, or both.

4.2.4 Development of Hotter Flames
It had become clear that a number of additional elements, although potentially amenable to measurement by atomic
absorption, were not readily available because they were very difficult to atomize. These included important elements such as aluminum, titanium and silicon. These, and many other, elements readily formed very stable monoxides in the flame and at the temperature of the air–acetylene flame produced virtually no free atoms. Attempts were made to use total consumption burners, with various modifications, in order to use the oxygen–acetylene flame, but these proved to be of limited success.

The design problem lay in the very high burning velocity of the oxygen–acetylene flame compared with the air–acetylene flame.

In a premixed system, where the fuel and the oxidant gases are mixed in a chamber before passing through the burner slot, it is of vital importance that the velocity of the mixed gases through the burner slot is never exceeded by the burning velocity of the mixture of gases. Should it do so then a “flashback” of the flame into the chamber will result in a severe explosion.

In designing a suitable burner for safe operation with an air–acetylene flame, the slot opening had to be reduced compared with the opening in use with air–coal gas. However, examination of the burning velocities for the acetylene flames, supported by air and oxygen, respectively, made it clear that a huge (and impractical) reduction in slot dimensions would be required to burn oxygen–acetylene safely in a premixed system.

Some developments were first made using physical mixtures of air and nitrogen, as the support gas, and successful determinations of aluminum, titanium, silicon and many other elements were achieved with this approach. Mixtures containing as much as 85% oxygen were investigated, albeit with some hazards.14

The use of nitrous oxide as a support gas, however, was a major breakthrough as it permitted the safe burning of nitrous oxide–acetylene using a burner with a sensibly reduced slot opening.15 As may be seen in Table 2, this flame provided a high temperature with a moderate flame velocity.

Compared with the potentially variable composition of a physical mixture of nitrogen and oxygen, nitrous oxide, on thermal decomposition in the flame, provides a mixture containing 67% (v/v) nitrogen and 33% (v/v) oxygen. However, it produces a flame more equivalent in temperature to that achieved with 50% N₂–50% O₂ owing to the exothermic decomposition of nitrous oxide.

With the additional use of this flame, a total of about 65 elements could, from 1965, be determined by AAS using flame atomization. More detailed examination of the flame atomization process will be presented later in this article.

### 4.2.5 Nebulizer–Burner Systems

Many different types of flame nebulizer–burner systems have been employed for atomic absorption. Some of these have been very useful for certain applications but for the purposes of this article the description will be confined to those commonly employed in available commercial instrumentation. A typical system is illustrated in Figure 14.

This system operates as follows. A flow of support gas (air or nitrous oxide), under pressure, passes into the nebulizer. The gas is expanded through a venturi throat and develops a pressure difference which draws a flow of sample solution through the inlet capillary. This solution, on emerging from the mouth of the venturi throat at a very high velocity, is shattered into droplets ranging in size from as small as 1–2 µm up to 100 µm or more, and this spray of droplets passes into the spray chamber. In this chamber, the oxidant gas and the droplets of sample solution are mixed with the fuel gas (acetylene). The flow spoiler, in this case a set of baffles, encourages the precipitation of the larger and heavier droplets of solution and these are drained from the chamber to waste. Most droplets larger than 10 µm in diameter will precipitate in the chamber. The mixture of oxidant, fuel and fine particles is burned in the flame.

A nebulizer–burner system with a glass impact bead. (Reproduced by permission of Varian Australia Pty Ltd. from Introducing Atomic Absorption, 1983.)

The aerosol then passes into the burner head and through the burner slot to the flame, burning above the slot.

A minor variation of the system illustrated in Figure 14 is shown in Figure 15. In this system, an impact bead, adjustable in position, is set in front of the nebulizer throat. When this is adjusted to its optimum position (which is critical), larger signals are produced, indicating that a greater amount of fine aerosol is being produced, presumably owing to the bead causing a more efficient shattering of the larger droplets into smaller ones. Both of these systems are in use in commercial instruments currently available.

Overall, the total nebulizer–burner system has changed little in principle since the 1950s when Walsh and his colleagues first used such a system to demonstrate the method.

Nebulizers were developed which were more corrosion resistant when it was realized that the solutions required to keep some elements in stable solution were very corrosive.

Early burner heads were of relatively light construction, but the development of the nitrous oxide–acetylene flame made additional demands. In particular, since the flame was much hotter, more robust construction was needed to avoid distortion after protracted use. Also, a more massive construction was needed to provide a better “heat sink” to avoid overheating, which could detonate the combustible mixture of gases in the spray chamber. In general practice today the above system is used with two different types of burner head. First, for use with an air–acetylene flame, a burner with a slot of dimensions 100 × 0.5 mm is used. For burning a nitrous oxide–acetylene flame, a burner with slot dimensions of 50 × 0.5 mm is suitable.

4.2.6 The Atomization Process in the Flame

As the aerosol produced from the sample solution passes into the flame, the first process will be “desolvation”, that is, the boiling off of the solvent (which is generally water). This will result in the production of extremely minute solid particles of the constituents of the dissolved material in the solution.

The effect of the higher temperature, as these particles move into the hotter part of the flame, will then be, in many cases, to dissociate the salts present and produce atoms of the constituent elements. However this is not always as simple as this might sound. Simple compounds such as NaCl and ZnCl 2 will very readily dissociate in the simplest manner possible, e.g. as shown in Equation (5):

\[
\text{NaCl} \xrightarrow{\text{heat}} \text{Na}^0 + \text{Cl}^0
\] (5)

where Na\(^0\) and Cl\(^0\) represent free atoms of sodium and chlorine. For many elements this simple process will apply in the air–acetylene flame. However, for some elements the process will be more complex and this may be represented for aluminum as Equation (6):

\[
\text{Al(NO}_3)_3 \xrightarrow{\text{heat}} \text{AlO} + (\text{various gases})
\] (6)

This is due to the great affinity for aluminum with oxygen and will occur regardless of which compound of aluminum is present. At the temperature of the air–acetylene flame, AlO is so stable it is virtually completely undissociated, so that no Al atoms are formed, and no atomic absorption signal can therefore be measured. However, at the temperature of the nitrous oxide–acetylene flame the next stage (Equation 7):

\[
\text{AlO} \xrightarrow{\text{heat}} \text{Al}^0 + (\text{O})
\] (7)

will occur. Most of those elements which demand the nitrous oxide–acetylene flame for atomization will react in this manner as most of them form very stable monoxide compounds.

Some elements occupy an intermediate position between these two extremes, and this may be typified with calcium. In this case it is appropriate to represent the reactions as Equation (8):

\[
\text{Ca(NO}_3)_2 + (\text{various gases}) \xrightarrow{\text{heat}} \text{Ca}^0 + (\text{O})
\] (8)

When air–acetylene is employed as the flame, the equilibrium represented is very much an incomplete reaction and only a portion of the calcium is converted to atoms. At the higher temperature of the nitrous oxide–acetylene flame, however, the equilibrium will be very much pushed
in the direction of almost complete production of atoms and greater sensitivity of measurement will result.

It is worth adding some comments here about the above description as it relates to the so-called “total consumption” burner. Such burners were developed to provide safe oxygen–acetylene flames for flame atomic emission measurement. In such burners, constructed as shown in Figure 16, all of the solution droplets pass into the flame, since there is no intermediate spray chamber.

Referring to the description above it follows that, since very many large droplets will pass to the flame, relatively large solid particles are formed following desolvation. These very large solid particles are poorly dissociated in the obviously very limited residence time available. Additionally, such burners provide a much lower temperature than the theoretical oxygen–acetylene flame temperature owing both to the lack of adequate mixing of the two gases and to the cooling effect of the larger solvent volume. All of these factors make such burners very limited as atomizers, whether used for atomic emission or atomic absorption, compared with premix systems such as those described previously.

It is worth pointing out that in the discussions above the accent has almost solely on the temperature of the flame atomizer. This is almost certainly the major factor, but it is not the only factor. The chemical environment of the flame is extraordinarily complex, and of course the chemistry of every single element which may be measured by atomic absorption is different from that of almost every other element. Flames used for atomization may, for simplicity, be classified as stoichiometric, fuel lean or fuel rich. A stoichiometric flame may be defined as a flame where the amount of oxygen present is exactly the amount required to totally burn the hydrocarbon of the fuel in conformity to the equation of the combustion process. For example (Equation 9):

$$C_2H_2 + 5N_2O \rightarrow 2CO_2 + H_2O + 5N_2$$ (9)

For any given fuel and oxidant combination the highest temperature will be provided by such a stoichiometric flame.

A flame which has an excess of the fuel gas present, compared with the amount of oxidant present, is classified as fuel rich, is sometimes also called a reducing flame and will be somewhat cooler than the stoichiometric flame.

However, for many elements, better atomization, as indicated by larger atomic absorption signals, will occur for mildly or even strongly reducing flames. Chromium in the air–acetylene flame is a good example of this, as is silicon in the nitrous oxide–acetylene flame. The full understanding of all of the processes involved probably still evades the scientific investigators of flame chemistry, but as will be discussed later, a practical means of achieving optimum adjustments is still attainable.

4.3 Vapor Generation Techniques

4.3.1 Mercury Cold Vapor

It has been pointed out earlier that mercury was measured by atomic absorption in the 1930s. Using flame atomic absorption, the sensitivity obtained for this element is very poor, particularly when viewed against the background that since mercury is a very toxic element it often needs to be determined at very low concentrations. However, it was found that mercury can be released from any compound associations in solution, and converted to elemental mercury, by adding a reducing agent (such as stannous chloride) to the solution. By bubbling a stream of a gas, such as nitrogen, through the solution the mercury atomic vapor is carried from the solution in this stream. The flow of gas is then passed through a flow cell placed in the light path of the atomic absorption apparatus, which then records the absorption signal. Because the reaction is fairly rapid, a very high transient concentration of atomic vapor of mercury is achieved, giving rise to a large absorption signal peak. Whereas flame methods only allow the detection of about 1 mg L$^{-1}$ of mercury, the “cold vapor” method permits the detection of small fractions of 1 µg L$^{-1}$.

In general, the equipment commonly used for this type of measurement is the same as that used for hydride methods employed for some other elements, and which will be described below.

![Figure 16 A total consumption burner. (Reproduced by permission of Wiley-VCH from B. Welz, Atomic Absorption Spectrometry, VCH, Weinheim, 1985.)](image-url)
In the case of stannous chloride the reduction reaction, in solution, is as shown in Equation (10):

\[ \text{Hg}^{2+} + \text{Sn}^{2+} \rightarrow \text{Hg}^{0} + \text{Sn}^{4+} \]  

(10)

It is also possible to use sodium borohydride (NaBH₄), as a means of generating hydrogen, as a reductant as described below for hydride methods.

4.3.2 Hydride Methods

Another group of metals, which exhibit poor sensitivities by flame atomization methods, may also be determined by a different vapor generation method. First suggestions of such an approach were made in 1969. As now employed, the addition of a sodium borohydride solution to an acid solution of the analyte causes the production of hydrogen, and this in turn induces volatilization of hydrides of these elements. Such hydrides may be typified by arsine (AsH₃), which has a very low boiling point and so is readily evolved from solution once formed. These hydrides are readily decomposed, in a quartz flow cell, at modest temperatures (800–1000 °C) to produce free atoms of the analyte. A diagrammatic representation of the principle is shown in Figure 17.

The quartz cell may be heated either by mounting it above a flame produced using a normal burner system or by electrically heating the cell. (Initially the method used was to add metallic zinc powder to the acidic solution, but sodium borohydride gives a faster and more reproducible reduction of the metal to the hydride. In both cases the reduction depends upon the production of nascent hydrogen.) This method is only applicable to those elements which readily produce hydrides of very low boiling point, viz. arsenic, antimony, bismuth, selenium, tellurium and tin.

Using this method, most of these elements have detection limits of <0.1 µg L⁻¹, whereas in the flame their detection limits are at best around 1000 times poorer at ca. 0.1 mg L⁻¹.

Lead has been determined by this technique but with some operational difficulty, which limits the appeal of the method for this element.

4.4 Graphite Furnace Atomization

This method was first described in 1961 and has been in use with commercial equipment since about 1970. It produces detection limits for many elements which are several hundred times better than flame detection limits of the same elements. It also has the advantage that only very small sizes of sample are needed (a few microliters compared with a few milliliters typically required for flame methods). It has the disadvantages of requiring a moderately expensive accessory apparatus and of being a very slow method. However, it is readily automated, which overcomes at least some of the disadvantages of the slowness. This method is outside the scope of this article and will be dealt with in detail elsewhere.

5 OPTICAL DESIGN OF INSTRUMENTS FOR ATOMIC ABSORPTION SPECTROMETRY

5.1 Atomic Absorption Spectrometer Design

Two basic types of optical system have been employed since the first atomic absorption instruments were produced commercially. These are the single-beam system and the double-beam system and simplified diagrams of such types are illustrated here.

In Figure 18 is shown a very simple single-beam system. This contains an absolute minimum of optical components and is therefore optically very efficient, and also relatively inexpensive. The major disadvantage of such a system is that any instability in light source output will result in a variable base line reading.

In Figure 19 is shown a simple double-beam system where the beam is split and two paths of light, one through the atomizer (sample beam) and the other around it (reference beam), are produced. These are subsequently recombined and both signals measured and compared with one another.

The obvious advantage is that since comparison of the two signals is continually and frequently being made, variations in source intensity are cancelled out. Two means of achieving this are in use in commercial instruments. That illustrated in Figure 19 employs a beam splitter and recombiner. The same result can be achieved by employing a system of chopping with a rotating mirror, as shown in Figure 20. In both cases the systems are not as simple as the single-beam system and consequently the cost is greater.
5.2 Optical Design for Background Correction

As mentioned previously, attenuation of the signal at the resonance wavelength by molecular absorption can cause errors in some cases, particularly when GFAAS is used. However, even in flame atomic absorption if the concentration of the analyte is low (giving rise to a very small atomic absorption signal), and the concentration of species producing molecular absorption at the analyte wavelength is high, errors will be introduced if correction is not made.

Figure 21 shows how a simple means of correction using a continuum light source may overcome this problem, a method first described in 1965.\(^{(19)}\) This is illustrated by comparison with the double-beam instrument shown in Figure 19, but such an approach can be similarly used with the systems illustrated in Figures 18 and 20.

Alternative measurements with the sharp line source and the continuum source will measure as indicated in Equations (11) and (12):

\[
\begin{align*}
\text{sharp line source} & = AA + MA \\
\text{continuum source} & = MA
\end{align*}
\]

where \(AA\) = atomic absorption and \(MA\) = molecular absorption. Subtracting the second reading from the first then gives (Equation 13):

\[
(\text{AA} + \text{MA}) - \text{MA} = \text{AA}
\]

Some of the radiation from the continuum source will be absorbed by atomic absorption. However, the instrument will be looking at the radiation from the continuum across a spectral band-pass of, say, 0.7 nm.
Since the atomic absorption will only be over an absorption profile maybe 0.01 nm wide, less than 1% of this radiation will be absorbed and as a first approximation this may be ignored with very little resultant error.

The situation is completely different for GFAAS methods. Here it may be commonplace for the background absorption to be of a magnitude which is greater than that of the atomic absorption signal. Very careful design of the background corrector and its very careful adjustment are then most important. For this reason, a much better means of background correction is the use of the Zeeman effect background correction system. This is outside the scope of this article since it is applied only to the graphite furnace method.
FLAME AND VAPOR GENERATION ATOMIC ABSORPTION SPECTROMETRY

6 PRACTICES OF ATOMIC ABSORPTION SPECTROMETRY

6.1 General

Like most spectroscopic methods, AAS is a comparative method, that is, it requires the calibration of the instrument with standards of known concentration before the analytical measurement of the samples may be made. However, as will be discussed later, it is generally not necessary to match the composition of the calibration standards to the samples with regard to elements other than the analyte. The calibration standards may generally be simple aqueous solutions containing nothing but accurately controlled concentrations of the analyte. Like almost all instrumental methods, the performance is limited by the signal-to-noise ratio, with regard to both the detection limit and the precision achieved. In the following sections, these factors will be discussed more and attention given to means of optimization in order to obtain the best possible detection limits and precision.

6.2 Optimization of Instrumental Parameters

Because the optimization process involves two factors, signal (size) and noise, it often involves some sensible compromise. This will be briefly discussed in relation to the various parameters which may be set by the operator of an atomic absorption spectrometer.

6.2.1 Hollow-cathode Lamp Currents

Referring to earlier discussion on line shapes, the selection of lamp currents is very much a compromise. As the HCL current is increased, two things occur. A stronger signal is produced but inevitably the line width of the emission signal of the resonance line is also increased. The first of these changes will allow the use of a lower gain in the photomultiplier and amplifier system and this will decrease the “noise” produced from the photomultiplier and amplifier system. However, the broader emission line will decrease the sensitivity and this will reduce the absorbance for a given concentration and may also increase the curvature of calibration. In method development, the best compromise should be experimentally determined with reference to obtaining the best detection limit and/or the best precision.

6.2.2 Wavelength Selection

In general, for a majority of elements, the most sensitive line will be used for the measurement. However, this is not always the case, and some brief examples will be mentioned. In the measurement of lead, the most sensitive line is at 217.0 nm and this will produce a signal, for a given concentration, which is about twice as large as that obtained if the 283.3-nm line is used. However, the signal at 217.0 nm has a much greater noise component because of two factors:

1. The photomultiplier response at 217.0 nm is much poorer than at 283.3 nm so the photomultiplier will have to be operated at higher dynode volts, giving rise to more noise.
2. At 217.0 nm the flame gases absorb more radiation than they do at 283.3 nm and so minor fluctuations in the flame will generate some noise.

As a result, the best signal-to-noise ratio and hence the best detection limits and precision will be achieved using the 283.3-nm line even though it has the lesser sensitivity.

For the measurement of low concentrations of nickel, the 232.0-nm line (which is the most sensitive line for nickel) is preferable. However, owing to a very closely adjacent (and virtually non-absorbing) line of nickel, curved calibration graphs are produced for this element, this effect becoming very pronounced at high concentrations. Obviously, at the extreme of curvature when the calibration graph becomes almost flat, measurement is no longer possible. If samples containing high concentrations of nickel are to be measured, the less sensitive line at 341.5 nm will provide almost linear calibration graphs over a wide range of concentration. Many similar cases may be cited—the rule should be that for optimum results each element and each application need to be investigated.

6.2.3 Monochromator Settings

The slit opening selected is generally a matter of recommendation by the equipment manufacturer as a function of the element to be measured and the wavelength to be employed. For example, considering the case of nickel discussed above, if this is to be measured at the 232.0-nm line a slit opening of, say, 0.2 nm should be chosen, rather than a wider slit to maximize the exclusion of the adjacent non-absorbing line of nickel. However, if the 341.5-nm line is used, a larger slit opening should be chosen to increase the light throughput as this will improve the signal strength. Since there are no lines closely adjacent to this line, this may be done with impunity.

6.2.4 Flame Selection

For those elements which are easy to atomize, the air—acetylene flame should be used. It is less expensive to operate and will give rise to better sensitivity than if the
nitrous oxide–acetylene flame is used (unnecessarily). In
general, nitrous oxide will be used for those elements
which are either atomized poorly, or not at all, with the
air–acetylene flame.

There are some elements which occupy a central
ground in this case. Elements such as calcium and
strontium are only modestly atomized in air–acetylene
and are subject to some interferences. By employing the
nitrous oxide–acetylene flame, not only is the sensitivity
improved but also the interferences are overcome. There
are a number of such cases and again for each element
the recommendations of the instrument manufacturers
need to be accepted or the actual element and sample
type need to be studied for each analysis by the analytical
chemist.

6.2.5 Flame Optimization

It should be understood that each element has its
own optimum atomization conditions, although for some
elements the differences between them may be relatively
small. This applies specifically to the composition of the
flame used and the position of the burner in the light path.

Some elements give a more efficient atomization,
resulting in a larger signal, if the flame is very “lean”,
that is, oxidizing or deficient in fuel. On the other
hand, certain elements, such as chromium, require very
‘fuel-rich’ flames, that is, reducing and having an excess
of fuel. Additionally for each element, and for each
flame composition, the portion of the flame in which the
maximum population of atoms occurs will be different.
Since the maximum absorption signal will result when
the beam from the HCL passes through this region of
maximum atom population, efforts must be made to
adjust the burner position to achieve this situation.

The best means of achieving both of the above two
optimizations is, while aspirating a solution of the analyte,
first to adjust the gas mixture to achieve maximum
absorption and then to adjust the burner position.
Sometimes, with elements for which the atomization
conditions are critical, more than one iteration of these
two adjustments might be necessary.

7 INTERFERENCES IN ATOMIC
ABSORPTION SPECTROMETRY

7.1 Spectral Interferences

This subject has been already covered in some detail.
True spectral interferences will only occur when an
absorbing line of another element overlaps the emission
line of the analyte from the light source and the
interfering element is also present in the sample. This
is, as previously stated, a rare occurrence and probably
all such cases have, by now, been documented in the
literature.

7.2 “Chemical” Interferences

Such interferences are sometimes also called “matrix
interferences”, and arise when an element, or compound,
present in the sample (but not in the calibration standards)
interferes with the production of atoms. A classical case
has already been mentioned in passing.

If a simple solution of calcium of a given concentration
is sprayed into the flame a certain reading will result.
If, instead of the simple calcium solution, one containing
the same calcium concentration, but also a significant
concentration of phosphorus, is sprayed into the flame a
much lower reading will be obtained. This is caused by the
formation in the flame of some calcium phosphate type
of compound which is harder to convert to atoms than
the CaO usually formed. Obviously one could match the
standards with the same P concentration but this would
require the prior determination of P in each sample.
Similar interferences will occur for all of the alkaline
earth group – Ca, Mg, Sr, Ba and Mg – in the presence of
P, Al and Si.

Such interference may be overcome in two ways:

1. By adding a large concentration of strontium or
lanthanum a competing mechanism is set-up. Because
the Sr or La is present in much greater concentration
than Ca, and because Sr and La are chemically similar
to Ca, the P will preferentially associate with the Sr
or La rather than the Ca. In practice, the Sr or La
is added both to the samples and to the calibration
standards.

2. If the nitrous oxide–acetylene flame is used, the
interference disappears because the flame is hot
enough to dissociate readily the compounds formed.

These are probably the most severe cases but minor
interferences of a similar nature occur with some other
element combinations and the literature should always
be consulted before embarking on any totally new
application.

7.3 Ionization Interferences

At the elevated temperatures occurring in flame atomizers,
the atoms of some elements will be ionized, that is,
the equilibrium shown in Equation (14) will occur:

\[
M^0 \rightleftharpoons M^+ + e
\]

where \( M^0 \) is the ground-state atom of element \( M \), \( M^+ \) is
the ion of the same element and \( e \) is an electron. Since
this particular atom is now an ion and not an atom it will not absorb radiation at the same wavelength. This effect will occur with elements that have ionization potentials which are low relative to the energy of the flame used for atomization. With air–acetylene flames significant ionization will occur only for the alkali metals, Cs, Rb, K and Na, all of which have very low ionization potentials.

In the much hotter nitrous oxide–acetylene flame, however, many elements will be significantly ionized. The most extreme are the alkaline earths, Ca, Sr and Ba, but ionization will also occur significantly for many elements such as Al and the rare earth elements.

The ionization reaction shown above, being an equilibrium, is subject to the law of mass action (Equation 15):

$$K = \frac{[M^+][e]}{[M^0]}$$

where $K$ is an equilibrium constant, $[M^+]$ is the concentration of the ion of the atom in the flame, $[M^0]$ is the concentration of the atom of the element in the flame and $[e]$ is the concentration of electrons in the flame.

If there is present in a sample, apart from the analyte, any element which readily ionizes (such as Na), then the additional electrons contributed to the flame by the ionization process will cause the equilibrium to shift back to the left in the equation and favor the production of more ground-state atoms. This will increase the atomic absorption reading. If the calibration standards have no sodium present then the readings obtained for the standards will be relatively lower. The net result will be a high result for the sample. In the case of the measurement of a number of samples with varying Na content, this will produce errors which will also vary.

To overcome this problem all solutions, calibration standards and samples should have added to them a large excess of a salt of an easily ionized element as an ionization suppressor. The most common such suppressor used is cesium, generally added as the chloride, which has the lowest ionization potential of all elements. This suppressor will ionize very substantially and in doing so will generate a high concentration of electrons. As described before, this high concentration of electrons will push the equilibrium back very strongly in the direction of simple (nonionized) atoms.

7.4 “Physical” Interferences

Some errors may also occur due to the physical composition of the sample solutions, by comparison with the calibration standard solutions. For example, if solutions of a solid sample are prepared by using high concentrations of sulfuric and/or phosphoric acid, the viscosity of the solutions will be high compared with simple aqueous solutions. This will diminish the uptake rate of the solution by the nebulizer and also will diminish the yield of fine spray to the burner. The error caused by this effect can only be prevented either by avoiding the use of such viscous acids or, if this is not possible, preparing the standards with the same concentrations of these acids. Similar viscosity effects may occur with very high concentrations of dissolved solids and again such problems can only be avoided in the same way.

The presence of a miscible organic compound may have the effect of reducing the viscosity of a solution and thus enhance the efficiency of nebulization. Ethanol, for example, will cause this effect. If an element in a sample of wine is measured by comparison with aqueous standards of the same element, high results will be obtained. Again, the solution to the problem will be to match, or at least approximate, the alcohol concentration of the calibration standards to that of the wine.

8 VALIDATION OF RESULTS OBTAINED BY ATOMIC ABSORPTION SPECTROMETRY

As may be seen from much of the preceding discussion, many factors may influence the veracity of results obtained using atomic absorption. In order to avoid errors due to an unexpected influence, it is wise to accompany any batches of samples analyzed with one or more standard reference materials, as close as possible in type to the samples. Control charts should be kept of the results obtained and remedial action taken if any deterioration in the quality of results is observed.

9 AUTOMATION IN ANALYSIS USING ATOMIC ABSORPTION SPECTROMETRY

Many automatic or semi-automatic atomic absorption spectrometers are now available. It is possible with such instruments, generally computer controlled, to store various parameters such as lamp currents, wavelengths, monochromator slit openings and flame gas flows. Although clearly such instruments are more costly, they do permit analyses to be performed by semiskilled operators once the parameters have been determined and stored by an expert analyst.

Automatic sample presentation to the instrument permits unattended operation, once a suitable type of automatic sampler has been loaded with samples and the analysis programmed. With instruments such as those described above, it is possible to measure sequentially a large batch of samples for more than one element as part of an automatic process.
Caution is suggested, however, with the totally unattended use of flame atomic absorption instruments for obvious safety reasons.

One of the most important developments for automated analysis by AAS is the use of flow injection analysis (FIA). This method represents a means of faster automated analysis and also permits minimization of the sample volume. Suitable FIA methods and equipment have been developed for use with flame and vapor generation methods of atomization. Details of such methodology properly belongs in an article on FIA and so are not considered further here.

10 COMPARISON WITH OTHER ANALYTICAL TECHNIQUES

10.1 Flame Emission
At the time when atomic absorption methods were first introduced, the obvious comparison was with flame atomic emission. Today it can safely be said that the atomic absorption method has all but replaced flame atomic emission in practical analytical chemistry.

FAAS provides a method which is rapid and easy to use, combined with simplicity of operation, and is not very prone to unexpected errors. It has a good sensitivity for most elements, adequate for many purposes. However, it measures only one element at a time and so is not particularly rapid for multielement analysis.

10.2 Inductively Coupled Plasma Atomic Emission Spectrometry
By comparison with FAAS, ICPAES is more sensitive for the more difficult to atomize elements such as B, W and Si, but is not as sensitive as some of the easy to atomize elements such as Zn and Cd. ICPAES methods, however, are ideally suited for simultaneous, or rapid sequential, multielement analysis and are thus faster than FAAS for this purpose.

In general FAAS instruments will cost less than ICPAES equipment and are easier to use. For the determination of low concentrations of elements such as As, Se and Hg, vapor generation AAS is more sensitive than ICPAES methods.

10.3 Inductively Coupled Plasma Mass Spectrometry
In more recent times, ICPMS has offered a much faster means of determining extremely small traces of most elements, and provides real competition for GFAAS. However ICPMS requires very expensive equipment and very skilled operation.

10.4 Choice of Methods
As discussed immediately above, there is major competition for AAS as a means of analysis. Certainly, for the determination of very low concentrations of several elements in large numbers of samples, ICPMS is probably the method of choice by comparison with graphite furnace AAS. The very high cost of the equipment and the high operating costs, plus the skills requirement, however, will keep the former technique out of the reach of most small laboratories.

In a similar manner, but to a lesser extent, ICPAES instruments offer some advantages for some users but remain less attractive to the smaller laboratory. It seems unlikely that major developments will occur in AAS to alter this scene. Rather, the inevitable lowering of costs for ICPAES and ICPMS will make it increasingly hard for expensive types of AAS to survive. A versatile and major analytical service laboratory may certainly justify the installation of ICPMS, ICPAES and AAS with flame, vapor generation and furnace modes.

In such a situation, the desirability of having individual AAS instruments for flame and furnace operation should be considered for the sake of convenience and the avoidance of contamination of the clean environment needed for graphite furnace methods. With such a versatile combination, the advisability of having a Zeeman background-corrected furnace instrument might also be considered.

11 FUTURE DIRECTIONS
Because of the lower costs of equipment and the simplicity of operation, AAS appears to be likely to continue to be attractive to most analytical laboratories, particularly the smaller ones. It also seems, to the author, that low-cost atomic absorption modules, serving as specialized detectors, in association with sample preparation and handling techniques, such as those associated with flow injection methods, are one of the important directions in which development might occur. Such an approach would continue to use the highly specific capabilities of the atomic absorption method, which have made it so popular since its inception.

Flow injection analysis (FIA), developed originally for the automation of serial assays, has become a powerful tool most adequate for performing on-line any sample preparations before final measurement (e.g. sample dissolution, dilutions, matrix removal, preconcentration, etc.). It is not surprising that the combination of FIA with atomic spectrometric techniques has enlarged the analytical potential of atomic methods and expanded their wide field of applications. The collection of sample manipulation processes which can be covered today by flow operation procedures is amazing and therefore the general instrumentation required is reviewed in this contribution.

The description of the different flow strategies is carried out according to a hierarchy going from simple dilutions (including isotopic dilution of particular interest when using mass spectrometric detection), reagent mixing or standard additions, to more sophisticated flow manifolds such as those based on the use of two phases (e.g. gas–liquid, liquid–liquid or solid–liquid) for separation/preconcentration purposes. Modern approaches allowing for on-line decomposition/dissolution of solid samples (e.g. on-line chemical oxidation, photo-oxidation and microwave heating) are also described. Finally, manifolds for the in situ uptake of the sample and its complete on-line pretreatment are discussed.

The coupling of the above flow methodologies to a variety of atomization/excitation/ionization sources (flames, quartz tubes, graphite furnaces, inductively coupled plasmas (ICPs), microwave coupled plasmas, glow discharges (GDs), etc.) is detailed, in order to understand the usefulness of this combination both in atomic techniques based on photon measurements (absorption, emission and fluorescence spectrometry techniques) and on ions measurement mass spectrometry (MS).

1 INTRODUCTION

The progress and implementation of new techniques for the automation of sample preparation has improved the performance of sample pretreatment methods in the everyday work of trace element analytical laboratories. The processing of a larger number of samples per unit time, the improvement of the precision by minimizing sample contamination and human errors, the small sample volumes required and the decreasing costs (attributed to the reduction of both human participation and consumption of reagents), are among the goals which can be accomplished by automating the sample pretreatment step.\(^1\)

Automation can be achieved by one of the following three approaches, or by combination of two of them:\(^2\) using robots which imitate the way that samples are manipulated by human operators, by discrete systems (batch analyzers) in which each sample preserves its integrity in a vessel mechanically transported (by a belt) to various zones of the analyzer (where the different sample pretreatment steps are carried out), and by flow manifolds in which samples are transported in flowing streams.

Flow systems based on the use of a continuous stream of liquid or, much less often, a gas have reached a special interest. There are two types of flow analyzers: (a) gas segmented flow analyzers (originally developed in the 1950s and first commercialized by Technicon under the name of “AutoAnalyzer”), in which the flow is segmented by air bubbles aiming at preserving the integrity of samples, and (b) unsegmented flow analyzers, which can be classified according to whether samples are discretely injected FIA or continuously introduced into the system. Nowadays, the unsegmented flow analyzers are much more popular than the gas segmented flow ones.

The name of FIA was coined by Ruzicka in 1975\(^3\) and he is generally credited as father of this technique, although Sarbeck et al.\(^4\) published, back to 1972, a sample introduction approach for flame atomic absorption spectrometry (FAAS) which would be called today flow injection (FI) in its strict sense. The first reports on techniques explicitly defined as FI for atomic absorption spectrometry (AAS) were published in 1979.\(^5\);\(^6\) Since then, the connection of FI to atomic spectrometric detectors has been extremely fruitful in terms of instrumentation versatility and variety of applications, giving rise to a great number of publications.\(^7\)–\(^10\)

FIA can be defined\(^11\) as “information-gathering from a concentration gradient formed from an injected, well-defined zone of fluid, dispersed into a continuous unsegmented stream of a carrier”. Since this definition does not facilitate visualization of the instrumentation required and the analytical interest of this versatile sample manipulation strategy, both aspects will be emphasized in the following paragraphs.

The basic equipment needed in FIA is relatively low cost, mechanically simple, robust and easily incorporated in automated systems. Figure 1 shows a general diagram of the most basic FI manifold, including the most commonly used instrumental units. The carrier solution and reagents are pumped continuously through a long, narrow tube, while a well-defined sample volume is introduced into the carrier stream (e.g. with the help of an injection valve). After the reactions occurring in the FIA system, the product of the reaction, which is monitored at the detector, gives rise to a transient response. Precise pumping and injection allows for identical treatment of every sample and standard in the FIA manifold, and this has the important consequence that there is no need to be restricted to reactions in which the reactants are stable. Also, precise timing is not necessary to obtain stable products nor to form them instantly. The use of FIA systems brings about several important advantages as compared to their manual batch analogs, both in terms of enhanced sample manipulation and of analytical performance (see Figure 2).

The sample manipulation processes collected in Figure 3, covered today by flow operation procedures extend over a wide scope and the instrumentation required for most of them will be reviewed in this contribution. Such flow strategies can be classified according to a hierarchy going from simple sample dilutions before final measurement to the in situ uptake of the sample and its complete on-line pretreatment.

Although processes like dilution (including isotopic dilution of particular interest when using mass spectrometric detection) and reagents mixing or standard

additions, can be considered as the simpler pretreatment operations which can be carried out in flowing systems, however, they are none the less important and nowadays robust on-line flow manifolds are routinely used to face these sample pretreatment stages.\(^{12,13}\)

A most interesting advantage of flow systems derives from their ability to integrate non chromatographic separation/preconcentration techniques based on the use of two phases (e.g. gas–liquid, liquid–liquid or solid–liquid) with a continuous detector in a straightforward manner. The general aim of these on-line flow separation/preconcentration techniques is to provide two sample fractions: one would contain the analyte(s) enriched and free from potential matrix interferences, while the other fraction would contain the matrix. In some particular cases this fractionation can offer a simple means of speciation;\(^{14,15}\) however, general speciation problems demanding information on several compounds or species of a given element require more powerful separation techniques (e.g. chromatographic or electrophoretic in nature). Finally, it should be highlighted that the use of simple two-phase flow separation systems allowed a dramatic increase of analytical reproducibility achievable by atomic spectrometry indirect determinations of organic pharmaceutical products, as compared to batch procedures.\(^{16}\)

In a further extension of sample pretreatment processes enhanced by flow manifolds and keeping in mind that most atomic detectors are designed for the introduction of liquid samples, it is not surprising that a great deal of interest is attracted at present by the development of on-line flow systems allowing for the decomposition/dissolution of solid samples. Different approaches including on-line chemical oxidation,\(^{17}\) photo-oxidation\(^{18}\) and microwave heating\(^{19}\) have been successfully exploited for these purposes.

Moreover, the in situ uptake of samples straightforward from their source and their on-line pretreatment before atomic detection can be considered as the ideal to be pursued in terms of automation (see Figure 3). This goal has already been addressed and interesting manifolds (some already available commercially) have been proposed to carry out in situ environmental analysis, to wholly automate analytical measurements in the clinical laboratories (e.g. in vivo sample uptake of blood samples\(^{20}\)) and for industrial process control.

2 BASIC CONCEPTS AND OPERATION PRINCIPLES

2.1 Basic Principles of Dispersion

The basis of FIA analyses relies on three aspects which should be kept controlled and reproducible: (i) volume of sample injected into the flow manifold, (ii) dispersion of the injected sample throughout the conduits of the system,
(precise pumping is required), and (iii) timing for each sequence carried out in the flow system (i.e. mixing with other streams, time to reach the detector, etc.).

Precise pumping and injection leads to a precise flow movement in a given manifold, allowing for reproducible chemical and physical manipulations. This is the fundamental feature that makes FIA so useful as an analytical technique.\(^{(11)}\) In FIA, every sample and standard is subjected to identical treatment and measured after the same time interval, therefore, there is no need to wait to complete reactions.

In FIA analysis the profile “concentration versus time” observed at the detector, for an injected sample with an analyte concentration \(C_o\), is a peak. This peak is the result of the dispersion processes occurring to the sample in the flow. The ratio of the injected analyte concentration, \(C_o\), to the instantaneous concentration corresponding to any point of the sample volume reaching the detector, \(C_g\), is known as the dispersion coefficient, \(D_g\). In many cases, the value of the dispersion coefficient at the peak maximum, \(D\), is used as the parameter to characterize the extent of mixing in a given FIA system.

The main experimental variables increasing the \(D\) value include: increases of the length and diameter of the tube, increases of the average flow rate and detector volume, and increases of the corresponding molecular diffusion coefficient. On the other hand, the most common way to obtain decreased \(D\) values is to increase the sample volume injected (other methods include the use of packed tubes or the modification of the viscosity). In most FIA systems \(D\) values are higher than unity. However, whenever a preconcentration step has taken place, the resulting \(D\) values are lower than unity.

Laminar flows are obtained under the experimental conditions used in FIA systems, i.e. on average, the molecules on the flow follow stream lines parallel to the walls of the narrow bore tubing. The walls of the tubing produces a drag on the flow. Thus, a gradient between the center of the stream and the wall is formed (the plot of the velocity profile from wall to the tube center is a parabola) giving rise to concentration gradients.

Besides, the concentration gradients will produce the diffusion of analyte molecules during the movement inside the tube. This diffusion will be axial (along the length of the tube) and radial (across the tube). It is important to note that, in the case of radial diffusion, the sample molecules on the leading boundary which diffuse towards the walls enter slower moving stream lines while molecules of sample close to the walls diffuse towards the middle of the tube and thus moving faster (see Figure 4). As a consequence of these processes, an interdiffusion between sample and carrier takes place which dilutes the sample or, in the case that appropriate reagents are introduced, produces chemical reactions between components of sample and carrier.

In those cases requiring efficient mixing, other mixing mechanisms are added to this inherent interdiffusion process, such as the addition of other channels which merge with the sample at confluence points, the inclusion of mixing chambers, etc. Also, in some instances additional flow patterns to aid mixing are included, like bending or knotting the tube, packing a tube with glass beads, etc. Mixing of carrier streams in FIA procedures can be aimed at achieving on-line sample dilution, internal standardization, standard additions, chemical reactions, etc.

### 2.2 Chemical Reactions in a Flow

In many FIA procedures, a reaction between a component of the carrier stream and the analyte is needed to form a detectable product or when interference eliminations by chemical complexation are required. In both cases, a compromise between residence time and percentage of product formation should be chosen for maximum sensitivity: lower residence times would allow \(D\) decreases, however, product formation can be too low at short reaction times (in any case, it should be stressed again that, in many cases, chemical reactions do not need to be completed in FIA procedures).

In atomic spectrometry, on-line chemical reactions are increasingly exploited: (i) to form a volatile derivative of the analyte (e.g. hydride generation (HG)), (ii) to produce a hydrophobic analyte derivative able to be extracted on an organic solvent or on a hydrophobic solid surface, (iii) to fix and later release an analyte from an active solid support with chemical bonding groups, and (iv) to digest samples on-line (e.g. by chemical oxidation, with the aid of ultraviolet (UV) radiation, microwaves, etc.). There are also situations where the addition of a given reagent is required to promote a desirable reaction in the atomizer (e.g. the addition of lanthanum as releasing agent in FAAS).

### 2.3 Flow Injection and Atomic Spectrometry Combination

There are two basic modes for detection in atomic spectrometry: photons measurement: AAS, atomic emission
spectrometry (AES) or atomic fluorescence spectrometry (AFS) techniques, and ions measurement: MS techniques. A great variety of atomization/excitation/ionization sources is available to the analytical chemist in order to transform the analyte adequately for further measurement as ions or photons, including: flames, graphite furnaces and plasmas [e.g. ICP, microwave induced plasma (MIP), direct current plasma (DCP)], stabilized capacitative plasma (SCP), GD, etc.].

Basic concepts and instrumentation of atomic spectrometry are beyond the scope of this contribution, but such concepts and general applications can be found in general text books as well as in monographs. The most widely used instruments in atomic spectrometry are the FAAS, the graphite furnace atomic absorption spectrometry (GFAAS), also known as electrothermal atomic absorption spectrometry (ETAAS), and the inductively coupled plasma atomic emission spectrometry (ICP-AES) while flame atomic fluorescence spectrometry (FAFS) is used to a lesser extent. Also, the continuously growing technique of inductively coupled plasma mass spectrometry (ICP-MS) should be highlighted. Developments of all aspects of atomic spectrometry are still taking place exploiting FIA combinations with atomic spectroscopy and may be easily followed via the Atomic Spectrometry Updates review articles appearing in the Journal of Analytical Atomic Spectrometry of the Royal Society of Chemistry.

The combination of FIA strategies to atomic spectrometry has improved the analytical performance of such atomic instruments in terms of: (i) lower detection limits (through on-line preconcentration processes and matrix separations), (ii) greater accuracy (sample pretreatment is carried out in a highly reproducible fashion and contamination is reduced), (iii) high variety of samples can be directly processed (e.g. by on-line digestion) and, of course, (iv) higher sample throughput.

3 INSTRUMENTATION

3.1 Elemental Components of the Flow System

The three basic components of a flow manifold are the propulsion unit and the connecting tubes. Moreover, as was commented in the Introduction, special devices to allow for on-line separation/preconcentration/sample digestion, are becoming more and more popular inserted or integrated in the basic manifold.

3.1.1 Sample Introduction Systems

Two basic categories of sample introduction modes in FIA can be distinguished, namely volume-based and time-based. In the first case, samples are introduced in the FI manifold through an injection port, which consists of a septum or, most frequently, a valve. When time-based injection systems are used, the injected sample volume depends on the time period during which the sample is allowed to enter into the flow manifold.

In the early stages of development of FIA, the liquid samples were introduced with a syringe through a rubber septum. However, important disadvantages of this sample introduction mode were distortion of the stream movement, lack of reproducibility in the manual injection and leakage after repeated injections on the same spot. The number of designs described to improve the performance of the septum has been considerable and different volume-based systems were proposed such as double proportional slider valves, six or eight ports rotary injection valves, and hydrodynamic injectors (valveless systems), as well as time-based injection systems including approaches based on two variable-speed computer-controlled peristaltic pumps and a commutator at the merging point or timed solenoid injectors.

In Figure 5(a) the schematics of a commercially available six-way rotary valve are shown. The sliding rotary valve has an external loop determining the sample volume to be injected. To introduce a different sample volume the external loop has to be changed. This type of valve is the most frequently used.

Figure 5(b) shows the principle of hydrodynamic injection: the system is based on the introduction of the sample by a second propulsion system into a well defined volume of conduit of the main flow manifold and Figure 5(c) shows the schematics for a time-based/sample dilution system allowing for the injection of a sample plug having an exactly predetermined concentration profile for the measured analyte.

Common insertion ports for the introduction of gaseous samples are gas-tight rotary valves and also the so-called ‘exponential dilutors’ consisting of a magnetically stirred chamber of known volume, where the sample is diluted in the carrier gas. Injections are made through a septum by means of a gas-tight syringe. A set of two valves (or a three-way stopcock) permits the chamber to be isolated from the carrier gas flow during injections (see Figure 6). After the sample is stirred for some seconds in the isolated chamber, the valves are open giving rise to a signal peak with an exponential decay as a function of time.

3.1.2 Propulsion Systems

The propulsion system has to provide a continuous and reproducible flow rate of the solutions passing through
in some cases, more than one solution has to be propelled and, therefore, multichannel capabilities are advisable.

Three main types of propulsion systems have been described:

1. Propulsion-less manifolds, which rely on the negative pressure generated by the nebulizer of an atomic detector to draw the liquid solution to the instrument.\(^{33}\)

2. Gas-pressurized carrier reservoirs.\(^{34}\) In this case, to keep a constant flow rate the pressure has to be maintained by means of a regulator. Although this system gives rise to a pulsed-free flow, drawbacks such as the consumption of gases or the difficulties to achieve constant flow rates have limited its use.

3. Pumps. Positive displacement pumps have been described as propulsion systems in flow manifolds; however, they introduce pulses in the analytical system and when two or more reagents are delivered in parallel these pressure pulses cause a non-uniform mixing of reagents reducing the accuracy and precision of the analysis. Although several depulsing systems have been described,\(^{35}\) this type of pump does not enjoy great popularity. The peristaltic pump is by far the most used type of propulsion system. These pumps allow to use more than one channel and to achieve a constant and accurate flow rate, which can be easily modified according to the analyst needs. The pumping rate provided depends on the rotation rate and the inner diameter of the pumping tubes. Peristaltic pumps tend to give slight pulses which can be almost eliminated by an adequate adjustment of the clamps pressing the peristaltic tubes or by the use of coils located in the manifold right next to the propulsion unit.

### 3.1.3 Connecting Tubes

Inert and flexible tubing with inner diameters in the range from 0.3 to 1.5 mm allows the connection of the different units of the flow manifold. In some parts of the system, the tubing could be bent to allow for an efficient mixture of reagents and sample. Also, multiway connectors are used to mix flows from different channels.

### 3.1.4 Two-phase Separation Units

In this section, only a brief introduction to the basic instrumentation needed for gas–liquid, liquid–liquid and solid–liquid separations in a flowing system will be presented. More details will be given in sections 5, 6 and 7 of this chapter.

#### 3.1.4.1 Gas–Liquid Separation

The co-occurrence of a gas and a liquid phase in a hydrodynamic system
to achieve a two-phase separation gives rise to problems which call for ingenious technical solutions.\textsuperscript{36–38} Gas liquid separators (GLSs) to be used in continuous separation systems should work smoothly and regularly to avoid lack of reproducibility and signal fluctuations and they should induce minimal dispersion or dilution of the gas phase (vaporized analyte). Many different designs have been evaluated as GLSs. The most common ones consist of a chamber, typically made of glass, in which a smooth separation between gases and liquids is aided by employing an inert purge gas. The use of gas permeable membranes, either flat\textsuperscript{37} or concentric hollow cylinders\textsuperscript{38} has been also described to separate both phases in flow systems. Examples of different GLSs used in flow systems are depicted in Figure 7.

3.1.4.2 Liquid–Liquid Separation A flow liquid–liquid extractor consists of a device able to merge two non miscible liquid phases to produce a single segmented flow, within which mass transfer takes place; the segmented flow passes through a phase separator, emerging from it as two separate streams, containing one phase each. The liquid–liquid phase separator must work efficiently and rapidly. There is a large variety of phase separators, based on two main principles, namely: density differences between the phases and selective wetting of appropriate inner surfaces. The most popular designs are based on the use of hydrophobic membranes which are only permeable to the organic solvent.

3.1.4.3 Solid–Liquid Separation Three main approaches have been described: sorption on a solid phase, generally consisting of a minicolumn, inserted in the flow system,\textsuperscript{26,39} precipitation and co-precipitation, based on the combination in a flow of three processes: precipitation of the analyte, its filtration and final dissolution,\textsuperscript{40} and anodic stripping, consisting of the use of flow electrolytic cells to eliminate nondepositing sample matrix components and to preconcentrate analytes which are deposited at the working electrode.\textsuperscript{15}

3.2 Assembled Flow Systems

Several companies are marketing sample introduction flow systems allowing for automated preparation of the most varied sample matrices. Representative examples of manifolds allowing for several sample pretreatment operations are reviewed below and in the next sections. However, it is important to emphasize that the modular character of these manifolds allows to adapt them to almost every particular sample pretreatment needed.

Figure 8 presents several diagrams of different configurations of basic flow manifolds. The addition of a second channel to the system depicted in Figure 1 allows some manipulations or pretreatment of the sample (Figure 8a) such as dilution and addition of reagents or masking agents, while the set-up depicted in Figure 8(b), called “merging zones”, permits important savings in reagent consumption\textsuperscript{41} and is also of interest for on-line dilution or standard additions.
Figure 8(c) shows a manifold to inject simultaneously several plugs of a given solution into the same carrier stream to achieve overlapped zones as a consequence of dispersion and thus permitting the analysis of a wide range of analyte concentrations\(^{42}\) and Figure 8(d) collects the schematics of a system to obtain a variety of dilution factors for a single injection without the need for controlled timing of any operation.\(^{43}\) The manifold consists of a three-branch network giving three partially overlapping peaks and five measurement points, three maxima and two minima.

Detailed instrumentation for separation/preconcentration manifolds including a solid–liquid, liquid–liquid or gas–liquid phases separation units as well as tandem on-line combinations of more than one separation strategy is thoroughly reviewed in sections 5 to 7 and the reader is addressed to those sections for specific information.

The possibility of carrying out decomposition/dissolution of solid samples on-line with the detector is attracting also a great deal of interest. Besides, in order to achieve volatile species generation from different analyte compounds, some organospecies need first to be decomposed, being this approach particularly interesting in metal speciation for species decomposition at the interface between the exit of a liquid chromatographic column and the atomic detector. Different approaches for on-line digestion of samples will be illustrated in section 8 in more detail.

### 3.3 Interfaces between Flow Systems and Atomic Detectors

The advantages of using flow manifolds as sample introduction systems for atomic detectors have been demonstrated for a variety of techniques including different atomic sources and/or detectors characterized by continuous operation (e.g. FAAS; ICPAES; MIP, SCP, and GD combined with AES; ICPMS, etc.) and even interesting approaches have been proposed for GFAAS, notwithstanding its discontinuous operation.

#### 3.3.1 On-line Coupling to Continuous Atomic Spectrometric Detectors

The interfacing of flow manifolds to continuous atomic spectrometric detectors for the introduction of liquid samples requires usually a nebulizer and a spray chamber to produce a well-defined reproducible aerosol whose small droplets are sent to the high temperature atomic cell.

In FAAS, the concentric pneumatic nebulizer is the most frequently used.\(^{44,45}\) Appleton and Tyson have given a theoretical modeling approach for nebulizer behavior in FIA coupled with FAAS.\(^{44}\) The suitability of the response kinetics of the FAAS as well as the contribution of individual components to the overall dispersion of an injected sample has been investigated by Fang et al.\(^{45}\) being observed that the dispersion effects in the nebulizer–burner system generally showed a very limited contribution to the dispersion of the injected samples.

The following guidelines for optimum performance in terms of sensitivity and precision when using a barrel nebulizer and FAAS detection were given by Brown and Ruzicka:\(^{46}\) (a) the flow rate of the carrier pumped into the nebulizer, should always be greater than the natural aspiration rate of the nebulizer; (b) the sensitivity is a function of the flow-rate of the carrier stream entering the nebulizer and the aspiration rate of the latter; (c) to achieve an optimum flow through the nebulizer, an additional stream may be added to augment the flow of the carrier without a significant decrease in sensitivity due to dilution.

Concerning plasma-based atomic sources, the more commonly employed is, by far, the ICP which was first used for AES and, more recently, for MS detection. A variety of nebulizers have been described for ICP work\(^{47}\) including cross-flow pneumatic nebulizers, pneumatic concentric nebulizers, Babington pneumatic nebulizers, ultrasonic nebulizers, microwave thermospray nebulizers, jet impact nebulizers, electrospray, microconcentric nebulizers, oscillating capillary nebulizers, direct injection nebulizers, etc.

In the 1980s much research work was devoted to the search of the “ideal” nebulizer, most of these designs also being tested as FIA interfaces to the plasma. It should be perhaps highlighted the direct injection nebulizer, ideally 100% efficient at transporting the introduced analyte into the ICP\(^{48}\) (the relative detection limits found for 30\(\mu\)L sample injection volumes were generally comparable to those obtained for continuous sample introduction into a conventional cross-flow nebulizer), the microconcentric nebulizer, inserted directly into the tip of a conventional sample introduction tube on an ICP torch to allow for a low dead volume interface,\(^{49}\) or the thermospray interface allowing for 10 fold better FIA detection limits as compared to FIA cross flow.\(^{50}\)

Probably the most frequently used spray chamber in ICP is the Scott type. However, a new type of spray chamber combining gravitational, centrifugal, turbulent and impact loss mechanisms in one apparatus to remove large droplets, increase transport efficiency and reduce memory effects was designed and evaluated by Wu and Hieftje;\(^{51}\) this chamber has at least 30% higher sample utilization efficiency, 2–3 times shorter sample clean-out time, half the cost, and simpler construction than the Scott type; moreover, it offers better detection limits and precision and when it was investigated for FI combined with plasma AES, the same sensitivity of
detection was achieved by continuous nebulization than injecting volumes of 200 µL.

Considering alternative plasma sources to the ICP, the low-power MIP should be highlighted. This excitation source is inexpensive and simple to operate, but its major limitation is the low tolerance to liquid samples and susceptibility to interferences caused by easily ionized elements. However, a MIP source called microwave plasma torch (MPT), unlike more conventional MIP supporting torch/cavities structures, tolerates aqueous aerosols and molecular gases introduced into the discharge. A study exploring the potential of the FI mode for sample presentation to the MPT/AES with an ultrasonic nebulizer allowed the reduction of memory effects of this nebulizer without loss of sensitivity or precision. Furthermore, by appropriate choice of sample dispersion, a significant reduction of the Na and K interferences were observed.

The introduction of analytes as gaseous derivatives offers special advantages in terms of sensitivity in atomic detection since 100% of the volatilized analyte goes into the atomic detector as compared to 1–5% of analyte introduced by liquid nebulization. The earliest flow volatile analyte generation systems connected on-line to ICPAES and AAS detector systems for the analysis of some metals and metalloids were reported in 1978 and 1982, respectively, and they have been also coupled to other atomic excitation sources such as the MIP and GD for AES detection. Besides, AAS and AES, AFS and MS detection has been successfully employed as detectors for these manifolds. Using quadrupole-MS detectors, the elimination of matrix interferences in some particular applications is required and flow systems based on the formation of a gaseous analyte derivative can overcome these problems: for example, selenium is one of the most difficult elements to be determined sensitively by ICP combined with GC. However, a MIP source called microwave plasma torch (MPT), unlike more conventional MIP supporting torch/cavities structures, tolerates aqueous aerosols and molecular gases introduced into the discharge. A study exploring the potential of the FI mode for sample presentation to the MPT/AES with an ultrasonic nebulizer allowed the reduction of memory effects of this nebulizer without loss of sensitivity or precision. Furthermore, by appropriate choice of sample dispersion, a significant reduction of the Na and K interferences were observed.

The intrinsic discontinuous nature of the GFAAS technique has limited the interest of interfacing basic continuous flow manifolds to this detector. However, several flow approaches which will be further detailed in the next sections, offer some capabilities favoring their exploitation as important aids in GFAAS work. These approaches include:

- Separation and preconcentration by on-line column sorption, coprecipitation and solvent extraction, as a consequence of the compatibility of organic solvents with GFAAS;
- Formation of volatile derivatives of the analyte and their preconcentration on a graphite tube ("in situ trapping");
- Slurry sampling: although solid samples may be placed directly in the graphite furnace, the coupling of slurry sample introduction systems to GFAAS is proving to be very promising and versatile.

4 FLOW INJECTION ANALYSIS

4.1 Automated Variable Dilution

Most FI procedures give rise to an inherent dilution of the sample, i.e. dispersion coefficient higher than one. This dilution can be particularly notorious if additional channels (and the corresponding mixing points) or strategies such as mixing chambers are introduced into the manifold.

There are a large number of possibilities for the use of FI techniques to control dilution of stock solutions or samples. According to Fang, FIA dilution systems are based on two basic mechanisms: sample dispersion (the measurement of the dispersion coefficient at different points of the peak profile is equivalent to the measurement of different dilutions of the injected sample) and flow manipulations (e.g. merging-flow, split-flow, etc.). Examples of strategies proposed in atomic spectrometry for on-line dilution, very useful also for standardization using a single standard, are summarized below:

- Variation of sample volume: changing the sample loop, a linear dilution of the standard solution injected can be obtained.
- Variation of the mixing coil dimensions: higher dispersion of the sample bolus, and therefore higher dilution of the sample, can be achieved by increasing the length and the inner diameter of the mixing coils.
- Merging flows: merging the sample carrier with another carrier provides a linear dilution of the sample which depends on the sample injected volume, the manifold volume and the ratio between the two mixing flow-rates.

3.3.2 Semi On-line Coupling to Graphite Furnace Atomic Absorption Spectrometry

The intrinsic discontinuous nature of the GFAAS technique has limited the interest of interfacing basic continuous flow manifolds to this detector. However, several flow approaches which will be further detailed in the next sections, offer some capabilities favoring their exploitation as important aids in GFAAS work. These approaches include:

- Separation and preconcentration by on-line column sorption, coprecipitation and solvent extraction, as a consequence of the compatibility of organic solvents with GFAAS;
- Formation of volatile derivatives of the analyte and their preconcentration on a graphite tube ("in situ trapping");
- Slurry sampling: although solid samples may be placed directly in the graphite furnace, the coupling of slurry sample introduction systems to GFAAS is proving to be very promising and versatile.

4 FLOW INJECTION ANALYSIS

STRATEGIES INVOLVING ONE-PHASE LIQUID FLOW SYSTEMS

4.1 Automated Variable Dilution

Most FI procedures give rise to an inherent dilution of the sample, i.e. dispersion coefficient higher than one. This dilution can be particularly notorious if additional channels (and the corresponding mixing points) or strategies such as mixing chambers are introduced into the manifold.

There are a large number of possibilities for the use of FI techniques to control dilution of stock solutions or samples. According to Fang, FIA dilution systems are based on two basic mechanisms: sample dispersion (the measurement of the dispersion coefficient at different points of the peak profile is equivalent to the measurement of different dilutions of the injected sample) and flow manipulations (e.g. merging-flow, split-flow, etc.). Examples of strategies proposed in atomic spectrometry for on-line dilution, very useful also for standardization using a single standard, are summarized below:

- Variation of sample volume: changing the sample loop, a linear dilution of the standard solution injected can be obtained.
- Variation of the mixing coil dimensions: higher dispersion of the sample bolus, and therefore higher dilution of the sample, can be achieved by increasing the length and the inner diameter of the mixing coils.
- Merging flows: merging the sample carrier with another carrier provides a linear dilution of the sample which depends on the sample injected volume, the manifold volume and the ratio between the two mixing flow-rates.

3.3.2 Semi On-line Coupling to Graphite Furnace Atomic Absorption Spectrometry

The intrinsic discontinuous nature of the GFAAS technique has limited the interest of interfacing basic continuous flow manifolds to this detector. 4 FLOW INJECTION ANALYSIS

STRATEGIES INVOLVING ONE-PHASE LIQUID FLOW SYSTEMS

4.1 Automated Variable Dilution

Most FI procedures give rise to an inherent dilution of the sample, i.e. dispersion coefficient higher than one. This dilution can be particularly notorious if additional channels (and the corresponding mixing points) or strategies such as mixing chambers are introduced into the manifold.

There are a large number of possibilities for the use of FI techniques to control dilution of stock solutions or samples. According to Fang, FIA dilution systems are based on two basic mechanisms: sample dispersion (the measurement of the dispersion coefficient at different points of the peak profile is equivalent to the measurement of different dilutions of the injected sample) and flow manipulations (e.g. merging-flow, split-flow, etc.). Examples of strategies proposed in atomic spectrometry for on-line dilution, very useful also for standardization using a single standard, are summarized below:

- Variation of sample volume: changing the sample loop, a linear dilution of the standard solution injected can be obtained.
- Variation of the mixing coil dimensions: higher dispersion of the sample bolus, and therefore higher dilution of the sample, can be achieved by increasing the length and the inner diameter of the mixing coils.
- Merging flows: merging the sample carrier with another carrier provides a linear dilution of the sample which depends on the sample injected volume, the manifold volume and the ratio between the two mixing flow-rates.
• Time-based electronic dilution: consists of timing the readout delay following sample dispersion. This procedure is the basis of gradient techniques for standardization with a single standard.

• “Partial overlapping zones” strategy: based on multiple injections by using multiple loop valves or network manifolds, to obtain partial overlaps of sequentially injected sample zones which penetrate in each other. It offers a series of minima between neighboring zones where the injected samples are diluted to different degrees by the carrier.

• Mixing chambers: the exponential concentration gradient obtained by the dispersion of a discrete volume of a concentrated standard through a well-stirred mixing chamber provides a high dilution capacity.

• “Zone sampling” procedure: a portion of the dispersed sample is re-sampled from a section of the gradient and dispersed again.

4.2 Automated Addition of Reagents to Improve Analytical Performance

Addition of special reagents to the sample to improve the analytical performance characteristics of atomic spectrometry procedures could be classified in two groups:

1. Strategies for one phase flow manifolds, such as the use of releasing agents or ionization suppressors to overcome interferences in flames or plasmas, the method of isotopic dilution in ICPMS to improve precision and accuracy, the addition of stabilizers or the formation of slurries and the on-line digestion of samples.

2. Strategies involving two phase flow manifolds, needed for on-line chemical reactions to form a gaseous or a non water soluble analyte derivative or to retain/elute the analyte from a solid phase.

The measurement of isotope ratios in ICPMS can compensate for matrix effects and instrumental drift. In the isotopic dilution method, the isotopic ratio in a sample aliquot is modified by adding a spike enriched in one of the isotopes of the element to be measured. From the measurement of the relative abundance, R, of each one of the two considered isotopes, A and B, in the unspiked and the spiked sample, the concentration of the analyte can be calculated according to the formula:

\[ C = \frac{(A_{sp} - R \times B_{sp}) W_{sp}}{(R B_s - A_s) W_s} \]

being C the analyte concentration, A_s and B_s the mass percentage of A and B in the sample, A_{sp} and B_{sp} the mass percentage of A and B in the spike, W_i the weight of sample and W_{sp} the weight of the spike.

The on-line isotope dilution can be carried out by merging two carrier streams or by the simultaneous injection of two solutions into the carrier stream. Advantages of the use of the isotopic dilution procedures using an on-line flow mode include: (i) only the sample volume consumed for measurement is mixed with the spike (the rest remaining intact), (ii) ease of selection of the proper sample to spike ratio in unknown sample concentrations, and (iii) possibility to achieve simultaneously on-line spike dilution and on-line isotope dilution.

The on-line flow addition of components such as anticoagulants in whole blood analysis, acidic solutions to form slurries, chemical modifiers for ETAAS analyses such as the mixture 0.1 mol L\(^{-1}\) Mg(NO\(_3\))\(_2\) + 0.01 mol L\(^{-1}\) Pd(NO\(_3\))\(_2\) has also been described. Samples, in acidic media, can be on-line digested using microwaves. The degree of dissolution in the microwave cavity is mainly governed by three variables: microwave power, length and diameter of the tubing inside the microwave oven, and the acid slurry strength. This methodology has been already applied to a great variety of samples of clinical, biological and environmental interest, using FAAS, GFAAS, FAFS, ICPAES or ICPMS detection modes. Details about on-line microwave assisted digestion are given in section 8.3.

4.3 Standardization and Implementation of the Standard Additions Method

Besides the traditional use of a series of standards with increasing concentrations of the analyte, in FIA systems external calibration can be also carried out employing a single standard by following any of the on-line dilution strategies already described under the “automated variable dilution” section.

The standard additions method to correct for matrix interferences and the internal standard method to alleviate instrumental drifts can be also incorporated via FIA systems, giving rise to automated methods where the amount of solutions employed and the time and cost of the analyses are reduced. Procedures based on merging zones, partial overlapping zones, zone sampling, etc. can be readily implemented for these purposes.\(^{65}\)

5 FLOW INJECTION SYSTEMS FOR ON-LINE SOLID–LIQUID SEPARATION AND PRECONCENTRATION

Nowadays on-line solid–liquid extraction procedures, and in particular, methods based on sorption of the
analyte in columns and its subsequent release, are experiencing a great popularity for sample pretreatment because they can be coupled in a most straightforward manner to most atomic detectors. Simplified handling, reduced solvent consumption and increased preconcentration factors are among the favorable features of solid phase extraction procedures. Of course, the elimination of matrix interferences (e.g. alkaline and earth-alkaline elements in high salt content samples), is also another advantage of these couplings, which is important for ICP analysis (for example seawater, dialysis fluids, etc.) or in the frequent cases of eliminating polyatomic interferences using the popular quadrupole ICPMS. (58)

FI on-line solid–liquid separation and preconcentration methods for atomic spectrometry may be classified into three main groups, according to the separation principle used for retention of the analyte, namely: sorption, precipitation/coprecipitation and anodic stripping voltammetry (ASV).

5.1 Sorption

Many sorbents have been developed so far and some of them are marketed as prepacked minicolumns. The characteristic features of the on-line preconcentration flow systems demand some properties of the packing material which may be only of minor importance in batch or traditional column procedures, since for flowing systems the column material has to be reusable, the kinetic processes or reactions have to be rapid and the flow uniform. Therefore, the special requirements may at least include: high mechanical resistance (in order to withstand high flow rates through the column and to maintain long column lifetimes), good kinetic properties (analytes have to be rapidly retained and readily eluted) and low degree of swelling and shrinking when being transformed from one form to another or with change of solvent conditions (the swelling/shrinking of some resins will give rise to backpressure and non uniform flow patterns).

Sorption preconcentration methods can be divided into two general groups: (a) analyte ions are collected directly by immobilized counter ions (ion-exchange) or immobilized chelating functions (sorption of ions), and (b) metal ions are adsorbed on suitable phases (e.g. activated carbon, octadecyl functional groups bonded silica gel, etc.) as hydrophobic metal chelates, previously formed by reactions in solution (sorption of metal chelates). The eluents more commonly used in the first case are diluted acids, bases or complexing agents, while for the second, the chelates are most frequently eluted with hydroorganic solvents.

The sorption of ions involves the use of “solid active phases” containing a suitable ion exchanger, a chemical reagent or even bioorganisms, immobilized on the solid support packed in a minicolumn. The solid active phases can be purchased (e.g. Chelex 100, Muromac A1, EDTrA-cellulose™, 8-hydroxyquinoline (8Q) bound to controlled pore glass (CPG)-8Q, 8Q bound to cellulose, etc.) or prepared at the working laboratory. The most common chemical mechanisms for reagent immobilization on the solid support to prepare the solid active phase are: adsorption (frequently used for hydrophobic reagents such as dodecanylquinolin-8-ol which is effectively fixed to nonionic supports), ion-exchange (the reagent is bound to the support by ionic groups which are not involved in the reaction with the analyte, such as the binding of 5-sulfonic oxine to resins with ammonium quaternary groups) and covalent binding (the reagent is covalently bound to solid supports such as controlled pore glass, silica gel, cellulose, etc.).

Chelex 100 was the first packing material used for on-line column preconcentration(68) and it has been widely used since then. This resin contains paired iminodiacetate ions coupled to a styrene divinylbenzene support. Despite its success, Chelex 100 does not fully meet the requirements mentioned at the beginning of the section for an ideal packing since the resin is subjected to some troublesome swelling properties: the particle size depends very much upon the counterion. These problems have been successfully overcome by the use of countercurrent flow elution. The Japanese product Muromac A1 which has also iminodiacetic acid functional groups was reported to be free from the troublesome swelling properties of the latter and has been used in a number of FAAS and ICPAES applications(69,70) however, the material does not seem to be widely available and it was used mostly by Japanese workers.

The controlled pore glass-oxine is other frequently column packing material used in on-line preconcentration.(71) Its popularity can be probably attributed to its good mechanical and good kinetic properties derived by the immobilization of the oxine functional groups on easily accessible porous glass surface. Fibrous cellulose with EDTA groups (EDTrA-cellulose™)(72) and oxine immobilized on CM-cellulose (cellulose-8O),(73) are also commercially available. Both materials show high capacity, high exchange kinetics and good mechanical and chemical stability.

Also, it is interesting that a minicolumn made of sulfhydryl cotton has been proposed for the speciation of inorganic mercury and methylmercury.(74) at pH 3–4 only the organomercury species are claimed to be retained and not the inorganic mercury. On the other hand, several applications of activated alumina in continuous flow-systems have been described both in the acidic form for the preconcentration of oxyanions and analysis by ICPAES(75) or in the basic form. In the latter case, the
The ability of bioorganisms such as algae to accumulate trace metals by biosorption has been known for some years. This effect was used in water treatment systems, however, only recently it has been exploited for analytical measurement methods. In 1991 the first application was described of columns with immobilized algae on-line coupled to atomic detectors for trace metal preconcentration being analytes eluted with diluted acids. Later, other applications such as the speciation of Cr(III) and Cr(VI) using an on-line column with immobilized algae has been also described.\(^{(78)}\)

The sorption of metal chelates opens also interesting possibilities.\(^{(39,79–81)}\) In this case the chelate is on-line formed in the flow system and then retained on a hydrophobic adsorbent, being later eluted with a hydroorganic solvent. The most commonly used reagents are dithio-carbamate derivatives, possessing very active sulfur binding sites. The most popular detectors for these applications seem to be FAAS and GFAAS (more compatible with hydroorganic solvents than plasmas).

Whenever the difference in the sorbent selectivity between the free chelating reagent and the formed metal chelate is small, the sorbent will absorb also free ligand (in addition to the metal chelate) during preconcentration. Once the capacity of the sorbent has been overcome, any remaining metal chelate still passing through the column will not be adsorbed. To avoid this problem, it has been proposed as strategy sorbing first a small amount of the chelating agent and then the analyte is preconcentrated by direct complexation with the solid sorbent agent.\(^{(82)}\) In this case, since both the chelate and the reagent are eluted, the column has to be fed with the reagent for each analysis. A comparative view of general advantages and disadvantages of metal chelates sorption, as compared to the sorption of ions, is presented in Figure 9.

![Figure 9](image)

**Figure 9** Comparison of “sorption of ions” and “sorption of metal chelates” procedures.

### 5.2 Precipitation and Co-precipitation

Continuous precipitation – filtration – dissolution processes can be described as continuous liquid–solid systems in which the second phase is first generated and then disappears in situ. The earliest flow on-line precipitation system with FAAS detection was reported by Valcarcel’s group employing on-line stainless filters to retain the precipitate. Usually, the precipitate is formed in the reaction coil, retained in the filter and subsequently dissolved by a suitable dissolution agent.\(^{(83)}\)

In 1991 Fang et al. presented an interesting approach based in analyte coprecipitation in the flow system. The analyte was coprecipitated quantitatively with the iron(II) – hexamethylenemmonium hexamethyleneedithio carbamate complex and collected in a “knotted reactor” made of ethyl vinyl acetate tubing. The precipitate was dissolved in isobutyl methyl ketone (IBMK) and introduced directly in the nebulizer of an FAAS.\(^{(84)}\) Similar approaches have been exploited successfully using this or other collectors in combination with FAAS and GFAAS.\(^{(40,85)}\) In comparison with online precipitation methods, coprecipitation procedures are less demanding on the solubility of the precipitate formed.

It is important to highlight how chemistry in precipitation and coprecipitation systems has some resemblance to metal–chelate sorption (the filter replacing the sorbent minicolumn), except that for precipitation/coprecipitation no column capacity limitations exist. Conversely, practical problems associated with continuous precipitation/coprecipitation systems can be encountered during the running of such manifolds.

### 5.3 Anodic Stripping Voltammetry

The use of flow-cells based on the principle of ASV coupled on-line to atomic detectors has also been investigated to obtain improved analysis of selected species (those which can be deposited at a working electrode and later released for atomic specific detection). These cells eliminate sample matrix components that are not electroactive and do not deposit during passage of the sample through the cell. Moreover, signal enhancement of analytes, as they may be preconcentrated at the electrode are obtained. Besides, in some cases ASV can allow for oxidation state speciation of elements: for example As(III) and Se(IV) are electrochemically responsive in most electrolytes while As(V) and Se(VI) are not.\(^{(15)}\) Thus, on-line ASV has allowed the speciation of both analytes in urine using ICPMS detection. Similar approaches have been also proposed for the speciation of Cr(VI) and V(V).\(^{(87)}\)
6 FLOW SYSTEMS FOR ON-LINE GAS–LIQUID SEPARATION AND PRECONCENTRATION

For some elements it is possible to increase the sensitivity of their atomic spectrometric determinations by generating a volatile derivative of the analyte outside the instrument and transporting it most efficiently to the atomizer.\(^{(86)}\) Strategies for such chemical vapor generation (CVG) include mainly: HG, cold vapor generation (CV), formation of alkyl derivatives and formation of halines.

Despite their advantages in atomic spectrometry, sample introduction methods based on classical batch analyte vapor formation procedures have a number of pitfalls, resulting in their replacement by flow-based methods. Their relatively modest throughputs, their bad precision (e.g., poor control over reaction conditions such as time), their lack of applicability to non stable analyte vapor derivatives, the use of quite large volumes of sample, and the generation of by-products, particularly hydrogen (when released as a sudden burst, it can affect negatively the flame or plasma) are detrimental to their analytical performance. Most of these problems can be eliminated, or at least reduced, by the use of flow procedures allowing for on-line vapor generation and gas–liquid separation. It is worth noting that such flow systems require reactions exhibiting high analyte volatilization kinetics (e.g., fast chemical reactions) and efficient mass transfer between both phases.

6.1 Flow Systems for the Formation of Volatile Hydrides of Metals and Metalloids

Chemical formation on a FIA system of covalent volatile hydrides of the analyte, has been widely applied to the atomic spectroscopic determinations of elements such as As, Bi, Ge, Pb, Sb, Se, Sn and Te.\(^{(89)}\) The earliest continuous HG systems connected on-line to ICPAES and AAS were reported by Thompson et al.\(^{(53)}\) and by Aström,\(^{(54)}\) respectively. In flow hydride systems, the sample (introduced either continuously or in the FIA mode) is on-line mixed with a reducing agent. In some cases additional channels are included for the introduction of other reagents (e.g., for on-line prereductions). The volatile species formed are separated from the liquid in a GLS with the aid of a continuous flow of a stripping gas (see Figure 10). The stripping gas and the volatile species (analyte derivatives plus by-products continuously produced such as H\(_2\), CO\(_2\) or water vapor) are continuously swept to the detector, while the liquid is driven to waste. Argon, at constant flow rate, is most frequently used as the stripping gas (examples of designs of GLSs are shown in Figure 7).

![Figure 10](basic_fia_manifold_to_achieve_gas-liquid_separation.png)
fact, surfactant aggregates can concentrate reactants at a molecular level and, therefore, change thermodynamic and kinetic reaction constants. Moreover, surfactants can solubilize, in a selective manner, analytes and reactants in the self-assembled “aggregates”. As a result, the special microenvironment existing in or on these aggregates may change the reactions (and so the observed interferences) in aqueous media.

6.2 Alternative Strategies: Cold Vapors, Ethylderivatives and Halines

The capability of mercury to form a monoatomic vapor at room temperature has been widely exploited in atomic spectrometry for its sensitive determination in the most varied samples. The reduction of mercury ions to Hg\(^0\) CV was first utilized in 1968\(^{91}\) to develop a CV with AAS “batch” analytical method for mercury determination. In recent years, most of the Hg analyses by CV technique are carried out by flow systems. Usually AAS detection,\(^{36,37}\) but also AES\(^ {92}\) or MS\(^ {93}\) are being employed for detection. Tetrahydroborate or tin(II) chloride are common reduction agents. The use of tin(II) chloride avoids the massive production of molecular hydrogen, which often deteriorates the performance of the spectrochemical plasma source. Conversely, it is important to point out that SnCl\(_2\) is not effective enough to reduce organomercury species. Therefore such organomercury species should be first oxidized to the inorganic form, preferably by resorting to a continuous on-line flow system.\(^ {17,19}\)

Mercury seemed to be the only metal proven to be able to form monoatomic vapor at room temperature. This property has been widely used to develop CV-atomic spectrometry techniques for very low levels of mercury as shown before. In 1995 evidence was shown\(^ {94}\) that cadmium is also able to produce ‘cold atomic vapor’ in appropriate conditions of reduction (e.g. surfactant-based vesicles). It appears that volatile cadmium hydride can be produced in the presence of several media and catalysts.\(^ {90}\) In this form, the metal can be transported to an absorption measurement cell where it dissociates spontaneously to atomic vapor of cadmium. More than 20 times improvements in Cd detectability have been demonstrated in this way by CV using flameless quartz tube with AAS,\(^ {94}\) in situ preconcentration and GFAAS,\(^ {62}\) CV with ICPAES\(^ {95}\) and recently by CV with ICPMS.\(^ {96}\)

Ethylation as a means of CVG is a promising (yet not fully explored) alternative to common HG and CV techniques.\(^ {88,97}\) The formation of volatile derivatives with sodium tetraethylborate is particularly interesting to enhance the detectability of some nonhydride generating elements (e.g. Zn, Cu, etc.) able to form ethylderivatives. Moreover, this type of derivatization is very useful to volatilize organospecies of Hg, Pg, Se, Sn, etc. (e.g. for speciation purposes), and is also of interest in the determinations of some hydride\(^ {98}\) forming elements which can be considered as ‘problematic’ such as Sn (high reagent blanks), Pb (low yield of HG generation) or Cd (unstable volatile derivatives). Recent work has also proposed the use of ethylation reactions in the presence of “organized media” (micelles and vesicles) in flow systems.\(^ {99}\)

Low power helium plasmas such as the He-MIP, the He-SCP or the He-GD possess high electronic temperatures allowing for good sensitivity by atomic emission determination of elements with high lying excitation levels in the visible region (e.g. most of the non-metals). Unfortunately, their rotational (kinetic) temperatures are so low that only gases or vapors are usually allowed in such plasmas. Thus, the chemical generation of chlorine, bromine, iodine, as a means of analyte introduction to these plasmas in flow mode has been successfully evaluated.\(^ {56,60}\) Different oxidizing mixtures were assayed such as H\(_2\)O\(_2\)/H\(_2\)SO\(_4\), K\(_2\)Cr\(_2\)O\(_7\)/H\(_2\)SO\(_4\), K\(_2\)S\(_2\)O\(_8\)/H\(_2\)SO\(_4\) and K\(_2\)Mn\(_2\)O\(_4\)/H\(_2\)SO\(_4\), the latter being the most promising for the simultaneous generation of the three above mentioned halines. Halide detection limits its achieved using such flow generation mode lie in the low ng mL\(^{-1}\) level using MIP,\(^ {59}\) SCP\(^ {59}\) or GD/AES\(^ {60}\) detection.

6.3 Approaches for Preconcentration in the Gas Phase

Further increases of analytical sensitivity can be obtained by in situ trapping of the volatile form of the analyte transported to an adequate trap of the vapor. The most frequently used approaches for the in situ trapping/concentration of analytes after chemical vaporization are: (i) amalgamation of Hg in gold and release by heating, (ii) retention of mercury or volatile hydrides on a slightly heated surface (normally graphite coated with noble metals) and release by further heating, (iii) cryogenic trapping of hydrides and subsequent release by removal of the cryotrap.

The amalgamation of mercury CV with noble metals, and its posterior release by heating, is a well established method (commercial equipment is available) to further concentrate mercury vapor. The trap usually consists of gold-coated silica powder, gold coated sand, or amalgams such as gold-platinum gauze.\(^ {56}\)

Other approaches to trap the vaporized analytes involve the use of cryogenic traps\(^ {100}\) or the retention of volatile hydrides on a slightly heated surface (normally graphite coated with noble metals) followed in both cases by metal release by further heating. This latter approach has found an important range of applications.
FLOW INJECTION ANALYSIS TECHNIQUES IN ATOMIC SPECTROSCOPY

in connection with final atomization by GFAAS. In this case, the graphite furnace is used as both the hydride trapping medium and the atomization cell. The hydride purged from the generator is trapped in the preheated furnace, usually in the range 300–600 °C, until the evolution of hydride from the sample is completed. The trapped analyte is subsequently atomized at temperatures generally over 2000 °C. The scope of this technique has been steadily expanding in the last decade comprising, for example, most of the volatile hydride forming elements, CV of mercury and cadmium, ethylated derivatives of Pb, Se, Cd, alkyl derivatives of As, Pb, Sn, etc.

The technique FI using CVG with GFAAS, which is now fully automated and is commercialized, enhances the sensitivity significantly and eliminates effectively the possible influence of the HG kinetics on the signal shape. The nature of the graphite tube is expected to affect greatly the efficiency of hydride adsorption. It has been shown that the coating of the graphite tube with Pd, Ir Zr, Ag or mixtures, improves the sensitivity and precision significantly.

The sensitivities achieved with the above mentioned gas phase preconcentration methods are very high and in most cases they are limited by the blank values, being a major contribution to the contamination by the analyte in the reagents. In this sense, approaches such as the use of immobilized tetrahydroborate could open a way for further improvements in detection limits.

7 FLOW SYSTEMS FOR ON-LINE LIQUID–LIQUID SEPARATION AND PRECONCENTRATION AND TANDEM ON-LINE COMBINATIONS

7.1 Flow Systems for Liquid–Liquid Extraction

Traditional set-ups (separation funnels) for liquid–liquid extraction usually require large vessels, large volume of reagents and laborious handling, being very time-consuming methodologies. To overcome most of these problems, the use of flow liquid–liquid extraction procedures has been investigated. A continuous liquid–liquid extractor includes a solvent segmentor, an extraction coil and a phase separator. The segmentor receives the streams of two non miscible phases and gives rise to a segmented flow; analyte mass transfer takes place through the multiple interfaces established throughout an extraction coil; finally, two separate streams (one with each phase) emerge from the liquid–liquid phase separator.

The liquid–liquid phase separator is probably the most important unit in the system. This unit must separate efficiently and rapidly the aqueous phase from the organic solvent in a continuous manner and its operation should be smooth and constant throughout.

Making use of differences in density of the two liquid phases and the selective wetting of inner surfaces, a variety of phase separators has been described. Figure 11 collects four representative examples of such devices. The separator depicted in Figure 11(a) is exclusively based on density differences between the phases: it

![Figure 11 Diagrams of examples of liquid–liquid separation units (not drawn at the same scale). sp: segmented phase; aqe: aqueous phase; org: organic phase. (a) Gravity-based separator; (b) PTFE-stainless steel gravitational phase separator. C: conical cavity, F: threading fittings, SS: stainless steel; (c) T-type separator; (d) membrane type separator. (Parts (a), (c) and (d) reproduced from Lin et al., Spectrochim. Acta, Part B 51, 1769–1775 © 1996; part (b) reproduced from Tao and Fang.101 © 1995, with permission from Elsevier Science Ltd.)](image-url)
consists of a conical device into which the segmented flow penetrates to form a single interface in the center. The flow of the lighter phase leaves the separator from its top while the heavier phase goes through the bottom of the device. To avoid large dead volumes in FIA systems, the volume of the inner cavity is of the order of tens of microliters. Figure 11(b) shows an improved gravitational phase separator.\(^{101}\) The separation unit was composed of two half blocks. The upper block was made from PTFE (poly(tetrafluoroethylene)), with a conical cavity and a single outlet for the separated phase, while the lower was of stainless steel, and furnished with an inlet and outlet for the segmented phase and waste flows, respectively. The dead volume of the conical cavity was about 45 µL. Other improved models, all-glass made based on density differences have been also proposed.\(^{102}\)

The T-type phase separator depicted in Figure 11(c) relies on both gravitational and selective wetting effects (as can be seen, it contains a whisker of fluoroplastics to assist the separation of the organic flow). The basic design of the membrane-based separators are shown in Figure 11(d). They are constructed with membranes which are permeable to most organic solvents but which repel aqueous solutions. The membrane is placed between two blocks. Once the segmented aquo/organic phase enters the lower part of the minichamber, the organic phase (lighter) passes across the membrane while the aqueous phase continues; thus, the two phases are separated. The membrane separator provides perhaps the best performance in terms of separation efficiency, reproducibility and applicability to a great variety of organic solvents; however, the short lifetime of the membrane is one of its serious practical limitations.

Important pitfalls of the liquid–liquid approach include: (i) the limited compatibility of organic effluents with plasma atomic sources, (ii) comparatively low enrichment factors for preconcentration purposes as compared to solid–liquid system (the actual enrichment factors depend on the flow-rate ratio for the two liquids involved and operational impediments preclude the use of highly different flow rates of the two phases), (iii) frequent problems associated to poor long term stability and robustness of the system requiring special operator skills.

Notwithstanding those limitations, flow liquid–liquid extraction systems have found important fields of application in connection with atomic detectors which withstand organic solvent introduction, such as FAAS and GFAAS. Finally, the use of these continuous separation systems for indirect analysis of organic pharmaceutical products should be highlighted here. Using the flow liquid–liquid separation strategy, it is possible to increase the analysis reproducibility as compared with the batch analogs, and some analyses would be only feasible when using these flow systems. For example, the determination of alkaloids has been described by formation of ion pairs between the sought drug and the inorganic complexes, BiI\(_4^-\) or Co(SCN)\(_4^2^-\), followed by liquid–liquid separation and measurement of bismuth or cobalt in the organic phase\(^{103}\) or the determination of amphetamines based on their reaction with carbon disulfide to yield diithiocarbamic acids; these acids reacted with Cu(II), Ni(II) and Zn(II) and were extracted with IBMK being the salts or complexes on-line detected with FAAS.\(^{104}\)

7.2 Integration of Two Continuous Separation Units: The Tandem On-line Concept

Occasionally, the complexity of the sample matrix or the sensitivity requirements may demand the use of more than one separation/preconcentration strategy to obtain appropriate analytical performance. Coupling two flow separation techniques in a tandem mode for sample preparation may be an effective solution to deal with such samples.

For example, we have seen that the sensitivity of analytical determinations by atomic spectroscopic methods can be enhanced by generation of volatile derivatives of the analyte. However, the chemical generation of these derivatives can be subjected to interferences (e.g. some metal transition ions in HG). Such interferences could be eliminated, for example, by using liquid–liquid or liquid–solid strategies. In this direction, a high degree of automation can be achieved by resorting to the ‘tandem on-line’ concept, i.e. the combination in a single on-line configuration of two continuous separation units: first, either a flow liquid–liquid extraction or a solid–liquid extraction step of the analyte; second, a volatile species generation from the second phase continuously fed to a gas–liquid separation unit; the first part allows improvements in both, selectivity and sensitivity, while the second permits the introduction of the analyte in gas phase to the detector, giving rise to further increases of the analytical sensitivity achievable.

This idea of “tandem on-line” separations for sample introduction in atomic spectrometry, was first applied to arsenic determinations in different samples by coupling in an on-line mode, a liquid–liquid and a gas–liquid separation device to an ICPAES.\(^{105}\) A limitation of the technique could be the degree of compatibility of the plasma source with the organic solvent used for the liquid–liquid extraction (a certain amount of volatile organic solvents can reach the plasma in the gas separation step). However, this problem is eliminated by using xylene to extract the analyte in the liquid–liquid separation process and by employing NaBH\(_4\) in dimethylformamide for the CVG process and final gas–liquid separation step. A similar “tandem on-line” concept has been extended to
indirect determinations of organic compounds\(^{(16)}\) and to metal speciation, such as the analysis of inorganic Hg(II) and methylmercury based on the selective liquid–liquid extraction of methylmercury, into xylene, as bromide and CV generation of atomic mercury from the organic phase.\(^{(106)}\)

Other on-line two-step approaches involve the elimination of interferences or the preconcentration of the analyte (prior to the HG step), using an ion exchange column (solid–liquid system), such as the manifold described for the determination of As, Sb and Se in a cobalt matrix.\(^{(107)}\)

### 8 FLOW SYSTEMS FOR FIELD SAMPLING AND ON-LINE DIGESTION OF SAMPLES

#### 8.1 Minicolumn Field Sampling and Flow Injection Analysis

The problem of securing during sample storage, an unchanged concentration of low levels of analyte or preserving the integrity of the species has received scarce attention from the analytical community both, for total metal and for metal speciation analyses. In recent years progress has been made in the development of true “field sampling” methods for the analysis of waters (seawater, river, lakes, etc.), which are mainly based on the isolation of the desired species in a stable form on appropriate minicolumns from which the analyte is later eluted for direct determination in the laboratory. A lateral advantage of this strategy is the easiness to transport, from the sampling source to the laboratory, small minicolumns containing the analyte (instead of transporting large containers with the liquid samples). This approach has been reported for the field sampling of Cr(III)/Cr(VI),\(^{(76)}\) inorganic and organomercury species,\(^{(74)}\) the determination of the ‘fast reactive’ aluminum fraction in waters,\(^{(108)}\) etc.

Minicolumn field sampling is readily implemented using basic FI equipment. The sample delivery system can be a syringe, in the simplest case, or a peristaltic pump (battery-operated pumps are available). Although different approaches are possible, the minicolumns are generally transported back to the laboratory after sampling and on-line eluted to the detector. On-line elution reduces the risk of sample contamination or loss; on the other hand, since small elution volumes are used, high preconcentration factors can be achieved.

Different solid active phases can be used as column packing materials for field sampling (reviewed in section 5.1). However, it is important to point out that for minicolumn field sampling, additional parameters such as column to column variability and stability of immobilized species adsorbed in the column are of particular relevance and should be studied carefully.

#### 8.2 On-line Photo-oxidation Flow Systems

The use of UV radiation to decompose organic matter is widely described in the literature; in particular, the oxidation reaction that combines a strong oxidizing agent with UV radiation has been described as an effective mode to destroy organic matter.

Concerning flow systems for analytical purposes, several photoreactor designs have been proposed to obtain the highest efficiency in such on-line decompositions. The favorable properties of PTFE for constructing tubular photoreactors is one of the most interesting features of this development, since in addition to its low UV absorption this material shows significant advantages over quartz coils, such as lower cost, easier handling and lower fragility. In atomic spectroscopy, most on-line photoreactors have been post-column coupled for metal speciation in hyphenated techniques using liquid chromatography for separation.\(^{(109)}\)

FI systems involving on-line photo-oxidation schemes have been also proposed. Figure 12 shows the schematics of one such manifold used for the determination of organoarsenic compounds by on-line arsine

---

**Figure 12** On-line flow sample digestion with UV radiation from a high intensity mercury lamp. (Reproduced with permission of Elsevier Science Ltd. from Atallah and Calman,\(^{(18)}\) © 1991.)
A mercury lamp (OD 1.5 cm, length 20 cm) is used as UV source. The lamp is wrapped with a coil of 5 m of 0.56 mm ID. PTFE tubing through which the sample flows. To increase the light intensity reaching the coil and to prevent eye exposure to UV radiation, the unit was enclosed in aluminum foil.

8.3 On-line Microwave-assisted Digestion

A priori, continuous microwave digestion in a flow was expected to be associated with serious problems derived from the vigorous chemical conditions (e.g. excess of acids), resulting elevated temperature, high pressure, and long digestion times, frequently required to obtain complete decomposition. On the other hand, an additional problem to be faced is the evacuation of the gases produced during the digestion step. However, interesting instrumental designs have been developed trying to solve creatively these problems.

The microwave oven can be incorporated into flow manifolds which may be off-line or on-line connected to the atomic detector. For example, in order to analyze samples requiring long digestion times, the flow can be interrupted for a period of time, while the sample is in the oven, resulting in stopped-flow digestion systems. A prototype of this type was developed by Karanassios et al. In their system, a sample plug was pumped into the center of the coil located inside the oven, but leaving about 50 cm of air at both ends of the tubing (110). During digestion, the sample slowly rotates inside the coiled tube; this rotation served as a stirring mechanism and also helped to reduce the effects of non-uniform microwave heating, due to the formation of ‘hot’ spots. The oven was modified by placing an electric fan to vent hot air during operation and to help cooling the tube at the end of the digestion.

Figure 13 illustrates the instrumental set-up for an on-line FI-microwave digestion system described by Haswell and Barclay, for the analysis of biological tissues using FAAS detection. (Reproduced with permission of the Royal Society of Chemistry from Haswell and Barclay, © 1992.)

Figure 13 Experimental set-up for an on-line microwave digestion FI system for FAAS detection. (Reproduced with permission of the Royal Society of Chemistry from Haswell and Barclay, © 1992.)

frequently needed. On-line continuous flow microwave digestions are ideally suited for FI using CVG sample introduction systems and have been extensively used to shorten the pre-reduction steps and to decrease the problems associated with the volatility and adsorption losses of analytes such as As, Sb, Sn, Sn, Pb or Hg during traditional extensive pretreatment procedures: microwave energy allows the rapid conversion of the analyte from its form bound to the organic matrix to a free inorganic appropriate oxidation step. The general procedure consists of first mixing the samples with an appropriate reagent, being the mixture transported in the flow to the microwave oven; the resulting digest is on-line mixed with sodium borohydride to form the corresponding volatile species which are swept into the detector. A bromination mixture (bromate/bromide) and persulfate in acidic media proved effective for the on-line speciation of selenium and determination of arsenic, antimony, tin and lead. Table 1 collects several examples of applications of on-line FI with microwave digestion coupled to a variety of atomic detection systems, which have been proposed by different authors.

Perhaps the more advanced degree of automation using flow systems has been demonstrated with an on-line microwave assisted mineralization manifold designed for in vivo sample uptake of whole blood samples (Figure 14).

The samples were drawn and pumped directly from the patient’s forearm to a timed injector. This injector was automatically controlled to inject into the carrier stream a mixture on-line formed between the sample, an acidic solution and an anticoagulant.Using this type of “closed-circuit” manifold, sample contamination problems from the environment should be reduced; besides, from the clinical point of view, it has also to be stressed that this type of manifold should eliminate risks of infection to nurses and analysts during the sample manipulation steps.

Before concluding this section it is important to point out that, although important progress has taken place in this field of on-line flow microwave digestion, the available instrumentation so far, does not yet seem to provide reliable performance. On a routine basis this technique needs further technical development to solve frequent malfunctions which will be probably overcome in the near future.

9 POTENTIAL APPLICATIONS PREVIEW AND FUTURE DEVELOPMENTS

As a consequence of the ever-growing number of chemical analyses routinely carried out, a major demand
in the area of research and development in chemical analysis is the need to make methods more cost-effective. On the other hand, the concept of quality is being fortunately installed in almost any aspect of our lives, analytical chemistry being a metrological discipline where the quality of results is of paramount importance. Hopefully, throughout this chapter it has become clear how both aspects could be improved by FIA methodologies.

There is a vast literature on the use of FIA techniques coupled to atomic detectors for a great variety of applications in different fields such as clinical, biological, environmental, etc. and several FIA methodologies, like volatile HG, are well implemented in routine analyses. However, the implementation of FIA strategies developed in research laboratories, in routine analysis is taking place at a slower pace, particularly for flow systems with higher degrees of complexity, even if they solve important problems. Since routine analyses demand robust instrumentation and procedures, this gap between routine practice and research laboratory work is being gradually reduced as reliable FI analyzers become commercially available.

From the upcoming research point of view, the great potential of the minicolumn ‘field sampling’ strategy should probably be highlighted; its merits have yet to be fully appreciated and exploited. Prospects for new developments and routine analysis in this area would be stimulated if custom sampling kits and minicolumn chemistries were commercially available. Also, the capability of flow systems to develop ‘uncontaminating’ methodologies, allowing sample contamination to decrease for modern ICPMS determinations and speciation cannot be overemphasized. The extreme sensitivity provided by this multielemental technique offers special attraction for its use in the analysis of very low level concentrations of any element and is unavoidable today for trace element speciation studies, particularly in biological systems. Besides, the ability of the ICPMS to accurately measure different isotopes opens new avenues in different fields such as in nutrition (e.g. to investigate the uptake of trace elements or their target organs and for identification of the source of environmental exposure to toxic elements). The simplification of the sample preparation steps and the reduction of contamination risks offered by FI methodologies, suggests that FI strategies will become the ‘natural’ sample introduction mode in the ICPMS as in other detectors.

The field of analytical atomic spectrometry has undergone profound changes during the last decade. A sort of “metamorphosis” is taking place at the sunset of this millennium: instead of looking for information on the atomic/elemental composition of matter (for many decades the goal of atomic spectrometry), we are witnessing a return of many atomic spectrosocists to look for molecular information (as aimed at for present element speciating problems). Of course, as atomic methods are intrinsically non-speciating (i.e. they destroy molecular information) the most popular approach to overcome the problem consists of coupling a separating unit (for compounds separation) on-line with an atomic detector (for final element-specific detection). Particularly the use of MS analyzers has revolutionized this field by offering unprecedented sensitivity and isotope measurement capability.

It is clear that atomic spectrometry will expand its “natural” scope in the next millennium into molecular information gathering as well. To do so, flow analysis techniques (FIA conventional strategies, chromatography and also capillary electrophoresis) will be synergically combined/integrated with the rich array of atomic/specific detectors at our disposal nowadays.

FLOW INJECTION ANALYSIS TECHNIQUES IN ATOMIC SPECTROSCOPY

Glow discharge (GD) sources provide analytically useful gas-phase species from solid samples. These sources can be interfaced with a variety of spectroscopic and spectrometric instruments for both quantitative and qualitative analysis.

### 1 Introduction

We have always questioned the physical make-up of our universe, but only recently has science advanced to the point that some of the most fundamental questions can...
be answered. While all fields of science play a role in information gathering, this is the specific charge of the analytical chemist. The field of analytical chemistry is broad, and although no one area can claim to be more valuable than another, the area of elemental analysis has always been critical to our understanding of the chemical and physical properties of materials.

Many years ago chemists characterized the world in terms of the basic elements of fire, earth, air, and water. Today, we classify our world in a similar manner, but in terms of carbon, nitrogen, oxygen, hydrogen, etc.; all that has really changed are the techniques we use – techniques that allow us to measure elemental and isotopic composition, elemental speciation, and spatial distribution of atoms and molecules.

This article focuses on two techniques used in elemental analysis: GD optical and mass spectrometries. We begin by describing the fundamental operation of a GD, including the sputtering and ionization processes. Next, we examine optical techniques that take advantage of the GD as an atomization source. Finally, we conclude by describing GD mass spectrometry, a powerful tool for multielement ultratrace analysis.

2 THE GLOW DISCHARGE

Although not always apparent, aspects of our everyday lives are permeated with technologies originally developed to solve scientific problems. An excellent example is the GD. Developed in the early 20th century as a spectrochemical ionization source used for fundamental studies of atomic structure, a variation of the same GD now illuminates storefronts in the guise of the common neon sign.

The GD is a simple device. Before delving into the fundamental processes that characterize the glow, however, it is useful to define a few terms. A GD is one example of a general class of excitation/ionization sources known as “plasmas”. This term refers to a partially ionized gas with equal numbers of positive and negative ions, and a larger number of neutral species. Often the terms GD and gas discharge are interchangeable. A GD can be formed in virtually any vacuum cell that can be equipped with an inlet for a support gas. A variety of geometries have been investigated in the past. Table 1 lists some of the most common. The most popular source is based on a cross-shaped vacuum housing that provides ports for spectroscopic viewing, sample introduction, gas introduction, and pressure and ion extraction.

2.1 Fundamental Glow Discharge Processes

The fundamental processes occurring in the discharge define a number of discrete regions. For the current discussion, only three regions – the cathode dark space, the negative glow, and the Faraday dark space – will be defined, because the other regions, while important, are often not visible due to limited separation of the cathode and anode. For a complete treatise on this subject the reader is directed to several excellent articles. The dark space regions are characterized by low light intensities relative to other regions of the plasma. This lack of luminosity arises from an absence of collisions and consequently the absence of excitation and the radiative relaxation events that produce photons. The cathode dark space is located between the cathode surface and the negative glow region. The presence of a large positive space charge in the negative glow causes the development of a potential gradient. The bulk discharge potential decreases rapidly through this region leading to

its common name, the cathode fall. This large potential gradient affects the acceleration of electrons that can ionize the discharge gas species and liberate secondary electrons in the negative glow which help to sustain the plasma. Radiative relaxation of species excited in the negative glow region yields the characteristic emission for which it is named. Because the major charge carriers in this region are electrons, the net space charge is negative. As electrons collisionally cool, they slow, decreasing their cross-section for excitational collisions with atoms. This smaller excitation cross-section results in the Faraday dark space close to the anode. Within this region the net space charge is zero and the potential gradient approaches a constant.

2.1.1 The Sputtering Process

The GD is of particular utility when analyzing solid conducting samples. Most competing techniques used for elemental applications (i.e. inductively coupled plasma mass spectrometry (ICPMS), flame spectroscopies, and graphite furnace techniques) require a sample in solution form to facilitate aspiration or introduction into the ionization source. The GD source possesses the inherent characteristic of producing gas phase analyte atoms directly from the solid conducting sample material. This phenomenon, known simply as cathodic sputtering, can be most easily described using a basic billiard ball analogy. Positively charged discharge gas ions are accelerated toward the negatively biased sample cathode. Prior to impact, these high-energy ions recombine with Auger electrons released from the cathode surface. The resulting high energy neutral species impact the surface of the cathode, transforming their kinetic energy (KE) into the lattice of the sample, thus causing a cascade of collisional events, much like the breaking of a racked set of billiard balls. If the resulting energy transfer is sufficient to overcome a surface atom’s binding energy, the atom will be released into the gas phase. The sputtering process liberates not only individual cathodic atoms, but also electrons, ions, and clusters of atoms and molecules. This process is illustrated in Figure 2.

Sputtered electrons are accelerated across the cathode dark space into the negative glow where they can contribute to excitation and ionization of gas phase atoms. The ions formed by the sputtering event do not travel far from the cathode but are returned to the surface by the effects of the electric field. Once in the gas phase, the analyte atoms and neutral clusters are free to undergo collisions that may dissociate clusters and redeposit atoms at the surface. A fraction of these neutrals...
diffuse into the negative glow where they undergo excitation/ionization.

The effect of an ion’s impact on the sample lattice can be measured by the sputter yield, $S$, as shown in Equation (1),

$$S = (9.6 \times 10^4) \left( \frac{W}{M} \right) i^* t$$

(1)

where $W$ is the measured weight loss of the sample in grams, $M$ is the atomic weight of the sample, $i^*$ is the ion current in amperes, and $t$ is the sputtering time in seconds. The ion current is related to the total current, $i$, by Equation (2),

$$i^* = \frac{i}{\Gamma + \gamma}$$

(2)

where $\gamma$ is the number of secondary electrons released, on average, by a single ion.

Much of the previous research involving sputtering has used secondary ion mass spectrometry (SIMS). Typically, ion beams generated from these types of sources are more tightly focused and of much higher energy than in GDs. This is important to note since there are a number of characteristics that affect the sputter yield for a particular system including the nature of the target, the nature of the incident species, the energy of the incident ions, and the angle of the incident ion beam.

2.1.2 Excitation/Ionization Processes

Although the atomization or sputtering process creates species essential for atomic absorption and fluorescence spectroscopies, it does not supply the excited species (such as ions) needed for atomic emission and mass spectrometric analyses. These excitation/ionization processes occur in the collision-rich environment of the negative glow. Collisions that occur within this region not only provide analytically useful species, but are also integral in maintaining the stability of the plasma. Figure 3 illustrates the two principal types of collisions that occur within the negative glow involving electrons, excited atoms, and ions. Excitation is dominated by electron ionization (Figure 3a), while ionization is governed by both electron ionization and Penning ionization (Figure 3b). These two processes account for roughly 90% of ionization occurring within the plasma. Electron ionization involves collision of an energetic electron with a gas phase atom. If the electron is of sufficient energy, it can interact with an electron in the valence shell of the atom, transfer enough energy to eject the electron from the atom’s electron cloud, and form an ion and a secondary electron. There is only a small probability that such a collision will result in ionization; this is zero below a threshold level, increasing at a rate of $C_1 C_2$, where $C$ is the excitation cross-section, as the electron energy increases. This can be explained using classical collision theory. At the threshold, only the complete transfer of energy will result in ionization. As the electrons increase in energy, collisions with only partial transfer of energy will result in ionization and the cross-section will increase. At high electron energies the time and wavefunction overlap is too short for ionization to occur, and the cross-section begins to decrease. The average energy of electrons found within the GD is not great enough to ionize most elements or the discharge gas. However, a Boltzmann distribution of energies predicts the presence of a small percentage of electrons with sufficient energy to ionize all elements. Chapman has performed calculations of the Maxwell–Boltzmann distribution of electrons to determine the percentage of electrons with energies above 15.76 eV, the first ionization potential of argon, the most common discharge gas. At an average energy of 2 eV, 0.13% of the electrons present are of sufficient energy to ionize argon. At an average electron energy of 4 eV, the percentage increases to 5.1%. A more thorough presentation of these calculations is given by Chapman.

Penning ionization, named after F.M. Penning who discovered the effect in 1925, involves the transfer of potential energy from a metastable discharge gas atom to another atom or molecule. If the first ionization potential of an atom or molecule is lower than the energy of the metastable atom, ionization will occur when they collide. Ionization cross-sections for most elements are similar for the Penning process, resulting in somewhat uniform ionization efficiencies. Metastable states are reached through either the activation of a discharge gas atom to an excited state from which radiative decay is forbidden or by the radiative recombination of discharge gas ions with thermal electrons. For argon, the most common discharge gas, the metastable levels are the $^3P_2$ and $^3P_0$ states with energy levels of 11.55 eV and 11.72 eV, respectively. Table 2 lists the metastable levels and energies of the discharge gases most commonly used.

\[\text{Figure 3} \] Illustration of the two major ionization pathways available in the GD plasma: (a) electron ionization; (b) Penning ionization.

to support GD plasmas. Metastable species are relatively long lived, existing for milliseconds under normal plasma conditions.18 Their longevity within the plasma, along with a relatively large ionization cross-section and energy sufficient to ionize most elements, make this process a major contributor to ion production. Investigations of ionization processes in steady-state DC-powered discharges have indicated that 40–80% of ionization occurring within these plasmas can be attributed to the Penning ionization process.19 Penning ionization also affords the unique advantage of discriminating against the ionization of discharge contaminants whose ionization potentials are greater than the metastable energy of the discharge gas atoms.

There are a number of other processes that play minor roles in ionization within the GD plasma. These processes involve charge exchange or associative ionization. Resonant charge exchange involves transfer of charge from one ion to an atom of the same species, while nonresonant charge exchange involves the transfer of charge from an ion to an atom of a different species. Associative ionization involves the combination of a metastable species with a gas phase atom to form a molecular ion with the liberation of a secondary electron. These processes contribute only marginally to ionization within the plasma but are the principal mechanisms by which interfering metal argide ions are formed.4

2.2 Radiofrequency-powered Glow Discharge Operation

Traditionally, most GD devices have used a steady-state DC-powered source; recently however, the utility of radiofrequency (RF)-powered discharges as sources for atomic spectroscopies and mass spectrometry has been investigated.21,22 A major advantage offered by the RF-powered plasma is the ability to analyze directly nonconducting samples such as ceramics and glasses.23 In the past, these types of samples were powdered, mixed with a conductive matrix, and pressed into a pin or disk to allow analysis by the DC GD.24–26 Utilization of an RF plasma allows the sputtering and subsequent analysis of these sample types without this added sample preparation step.

Current cannot propagate through an insulating material; when subjected to an applied DC potential, therefore, an insulator behaves in a fashion similar to a capacitor and begins to accumulate charge. With the application of a negative voltage, the surface potential of the insulating material decays to a more positive potential with time. This decay can be attributed to charge neutralization at the cathode surface. The DC discharge will sustain itself until its threshold voltage is reached and the plasma is extinguished. Application of a high frequency potential to a conductive material adjacent to the insulator will allow positive charges that accumulate at the nonconductor surface to be neutralized by electrons during the positively biased portion of the cycle. Therefore, application of a high frequency potential will allow a negative potential to be maintained on the nonconductor’s surface.

Figure 4 illustrates the phenomenon known as cathode self-biasing that allows the discharge to be maintained for lengthy periods of time.4 Self-biasing is based upon the mobility difference between ions and electrons.

![Figure 4](https://via.placeholder.com/150)

**Figure 4** Electrode response to an applied square wave potential: (a) $V_+$, applied voltage; (b) $V_-$, response voltage. (Reproduced by permission from B. Chapman, *Glow Discharge Processes, Sputtering and Plasma Etching*. Copyright (1980) John Wiley & Sons Ltd.)
As a negative potential is initially applied, the surface charges quickly, reaches a maximum, and begins to decay (Figure 4b). When the potential is switched, electrons are accelerated and bombard the surface much like the positive ions during the negatively biased portion of the cycle. The electrons, however, have a greater mobility than the more massive positive ions, therefore the surface potential decays more quickly. After a number of cycles, the waveform will reach a steady DC offset. This DC offset potential is approximately one half of the applied peak-to-peak voltage and sustains the sputtering ion current. The nonconducting cathode is alternately bombarded by high-energy positive ions and low-energy electrons that support the sputtering process. Operation in this mode has proven useful for the analysis of materials such as nonconducting alloys, oxide powders, and glass samples.\(^{(27)}\)

2.3 Pulsed Operation of the Glow Discharge

The GD plasma can be operated in a modulated power mode as well as the steady-state mode described previously. Pulsed power operation offers some distinct analytical advantages that make it attractive to the analyst.\(^{(28-32)}\) Steady-state discharges are power limited because increased power application results in resistive heating of the cathode, eventually jeopardizing sample integrity.\(^{(33)}\) Modulation of the applied discharge power permits operation at higher instantaneous power while keeping the average power at an acceptable level. This operation mode serves to increase the sputter yield by increasing the average energy and/or the number of incident ions while allowing the sample to cool during the off portion of the discharge cycle. Modulated operation also provides temporal segregation of discharge processes.

Modulated GD operation relies on a microsecond to millisecond square wave power pulse, with a duty cycle of 10–50%. These parameters allow sufficient time for cooling and for the removal of species from one pulsed event before the next one is initiated. Figure 5 depicts a typical pulse sequence showing both discharge gas (Ar) and analyte ion signal profiles. It is apparent that signal behaviors for discharge gas and analyte species differ dramatically. Upon power initiation, the discharge gas ion signal exhibits a sharp rise in intensity to a maximum\(^{(30,34)}\) (Figure 5a). This “prepeak” results from the electrical breakdown of the discharge gas species upon power application. The short delay occurs because the acceleration of electrons and subsequent electron ionization of the discharge gas are not instantaneous processes. In contrast, the analyte ion profile behaves differently (Figure 5c). A much longer delay occurs before a more gradual signal increase is observed. This delay arises because sample atoms must first be sputtered from the cathode surface and diffuse into the negative glow region before they can undergo ionization. The temporal correlation between the observation of discharge gas ions and the appearance of analyte signal can be seen in the figure. Both signals reach equilibrium conditions about half way through the applied power pulse during the “plateau” region. During this time regime the plasma most closely approximates the behavior of a steady-state plasma.

Upon applied power termination, the two ion profiles again show markedly different behavior. The discharge gas ion profile decreases quickly (\(\approx 500\) µs) upon power termination. Previous studies have explained this signal decay as the rapid recombination of discharge gas ions with thermal electrons to form metastable discharge gas atoms.\(^{(35,36)}\) The analyte ion profile quickly increases during the “afterpeak” region, reaching a maximum shortly after pulse power termination. This signal then decreases gradually to the baseline. Figure 5(b) represents the first derivative of the discharge gas ion signal profile. The maximum and minima observed in this portion of this figure represent the temporal location of the respective maximum signal intensity increases and decreases.

![Figure 5](image-url)
for the discharge gas signal. Interestingly, the maximum decrease in the discharge gas ion signal corresponds to the afterpeak maximum for the analyte species.\(^{29,30}\) This correlation supports the theory that at power termination electrons are collisionally cooled and recombined with argon ions, forming metastable species. This increase in metastable argon atoms increases the probability of ionization via the Penning process, thus providing enhancements in the analyte ion signal.

Temporally gated separation and detection of species found in these distinct plasma regions increases the utility of the GD devices.\(^{33,37}\) The most analytically useful region is the afterpeak. Data acquired within this time regime offer two advantageous characteristics. As illustrated in Figure 5(e), the signal intensity for the analyte species increases substantially, thus potentially enhancing the sensitivity for analyte species in this region. The other advantage arises from the suppression of electron-ionized interfering species.\(^{29,30}\) The first ionization energies of the discharge gas and molecular contaminants (e.g. \(\text{H}_2\text{O}, \text{N}_2, \text{O}_2\)) are too high to allow ionization through the Penning process. Upon power termination species that are ionized via electron impact are no longer excited. Thus, if the acquisition gate is moved far enough into the afterpeak, contributions from these species will be minimized.

### 2.4 Applications

In the early 1970s, as GD instrumentation and techniques were being transitioned from research applications to routine sample analysis, spark source techniques reigned as the analytical tool of choice for trace analysis of solids. Spark source spectrometry was limited, however, by its expense, complexity, and unreliability. These disadvantages associated with spark source spectrometry facilitated the acceptance of the GD for the analysis of solid samples.

#### 2.4.1 Bulk Analysis

Historically, GD mass spectrometry and optical spectroscopies have proven most valuable for the analysis of bulk conductive solid samples. As explained earlier, GD methods provide a representative gas phase analyte population directly from samples in the solid form, thus dramatically simplifying sample preparation. GD techniques can also be used for the analysis of nonconducting samples such as glasses, polymers, and ceramics.\(^{38–40}\) The first analyses of nonconducting materials involved mixing a powdered sample with an easily sputtered, conducting matrix, such as high purity copper or silver powder.\(^{41–44}\)

The mixture was pressed into a sample cathode using a die and hydraulic press system. Unfortunately, this complicated sample preparation, especially for samples that were not in powdered form. Homogeneity of the mixed sample also became of concern for the analyst. Two other methods for analysis of nonconducting samples have also be used. These methods do not require sample mixing but rather use an RF-powered or a secondary cathode GD source to sample directly solid nonconducting materials. Section 2.2 describes plasmas powered by RF sources. Secondary, or sacrificial, cathode GD systems utilize a monoisotopic conductive mask (e.g. Ta, Pt) that is placed on top of the sample to be analyzed. A potential is applied to the mask, which thus assumes the role of the cathode. As material is sputtered from the mask, a large portion of it is redeposited on the surface of both the secondary cathode and the nonconducting sample. At this point, the layer of cathode material deposited onto the sample becomes conductive and thus assumes the applied potential and attracts impinging ions. As ions impinge upon the cathodic layer, they ablate both the cathodic material and the underlying nonconductor, introducing both species into the gas phase for subsequent analysis. It is clear that the mask material must not contain species that are of interest because this will contaminate the sample and preclude accurate measurements. A number of references are available describing in detail the use of secondary cathodes.\(^{45–47}\)

#### 2.4.2 Surface Analysis

Recently, surface analysis by GD spectrometry has aroused great interest in the analytical community. In a sense, GD is always a surface analysis technique, acting as an atomic mill to erode the sample surface via the sputtering process. Atoms sputtered from the surface are subsequently measured using either optical or mass spectrometric techniques. GD sputtering consumes relatively large quantities of sample in a relatively short time period (up to milligrams per minute), making analysis of thin films (\(<500 \text{Å}\)) difficult to virtually impossible. Plasma conditions, along with discharge gas choice, can be adjusted to slow the ablation process, thus allowing the analysis of films with micrometer thicknesses. Figure 6 is a graphical illustration of a typical spectral intensity–time profile of a multilayer coating prepared by chemical vapor deposition of carbon steel. The outer layer consists of vanadium carbide and the inner layer chromium carbide. It is obvious from Figure 6 that signal responses do not follow an ideal square wave pattern for appearance and disappearance. Clearly, the metal sample layer is not all eroded at a well-defined time, but is scattered across a diffuse region that is gradually removed. This signal tailing is a manifestation of the redeposition that occurs from the plasma. It has been estimated\(^{48}\) that up to 67% of the sputtered atom population is returned to the surface by collisions with argon atoms, to
be resputtered before eventually escaping permanently from the surface. Redeposition, along with a relatively high sputter rate, prevents GD from being used to profile very thin films. By calibrating erosion rates using standard layered samples, the thickness of layers can be determined by analyzing the signal–time profiles, allowing the full characterization of sample layers.

### 2.4.3 Analysis of Solution Samples

Analysis of solutions has been performed using GD techniques even though their major advantage lies in the ability to directly analyze solid-state samples. It is important to note that aspiration of a solution directly into the GD will cause quenching of the plasma, making removal of any solvent from the sample preferable. The simplest and most direct method of doing this is to evaporate a solution onto a conducting cathode, leaving a dried residue as the sample. A more elegant method for depositing solution samples onto a cathode involves electrodeposition. This approach also permits analytes in large sample volumes to be preconcentrated before analysis. Solutions containing samples have also been mixed with a conductive powder and dried for subsequent analysis. This approach is similar to that used for the analysis of nonconductive powders.

Although limited by its difficulty, direct analysis of solution samples by GD techniques has been performed for specialized applications. Strange and Marcus have used a particle injection system to introduce a solution sample into the GD. Steiner et al. have also utilized a pulsed plasma TOF system to obtain concurrent elemental and molecular information for high vapor pressure liquid samples. For the foreseeable future however, GD techniques will likely remain focused on the analysis of solid-state samples.

### 3 SPECTROCHEMICAL METHODS OF ANALYSIS

The goal of the analytical chemist is often to identify a particular chemical species or to quantify the amount of that species in a sample. In a spectrochemical analysis, the chemist uses the intensity of radiation emitted, absorbed, or scattered by a particular species versus a quantity related to photon energy, such as wavelength or frequency, to make such measurements.

In this section, the basic requirements necessary to obtain a spectrochemical analysis are reviewed, along with three spectrochemical methods that are used to effect the measurement: AAS, AES, and luminescence spectroscopy. Although there are many variations of each of these methods, we will review only the classical approaches and the variations that have been used with GD devices. Table 3 summarizes the quantity measured and gives examples associated with each measurement technique.

### 3.1 Basic Requirements Necessary to Obtain Optical Information

For thousands of years scientists have been performing qualitative analyses based on color, smell, taste, size, and shape. Although first year college chemistry students

are still taught to use their senses to help identify substances in qualitative laboratory, for the rest of us these less precise approaches have been replaced with chemical and instrumental methods that can measure not only pure materials but trace components in complex mixtures. Most materials are not willing to give up this information spontaneously, however. Instead, to obtain chemical information about a sample, it is necessary to perturb the sample through the application of energy in the form of heat, radiation, electrical energy, particles, or a chemical reaction. The application of this energy often causes electrons in analytes to be excited from their lowest energy or ground state to a higher energy or excited state. Several spectroscopic phenomena depend on these transitions between electronic energy states. Information can be obtained by measuring the electromagnetic radiation emitted as the electron returns to its ground state from an excited state (emission), by measuring the amount of radiation absorbed in the excitation process (absorption), or by measuring the changes in the optical properties of the electromagnetic radiation that occur when it interacts with the analyte (e.g. ionization or photochemical reactions). Qualitative information is extracted by observing a particular element-specific transition, while quantitative information is obtained by quantifying the amount of radiation emitted or absorbed in that transition. Figure 7 is an illustration used by Ingle and Crouch to depict the many processes involved in converting concentration information into a number – the analytical chemist’s goal in making a measurement. A sample introduction system presents the sample to the encoding system, which converts the concentrations \( c_1, c_2, c_3 \) into optical signals \( O_1, O_2, O_3 \). The GD is somewhat unusual (compared with other atomic sources like the flame or the inductively coupled plasma) because it serves as both the sample introduction system (through sputter atomization) and the spectrochemical encoder. The information selection system (often a monochromator) selects the desired optical signal \( O_1 \) for presentation to the radiation transducer or photodetector. This device converts the optical signal into an electrical signal that is processed and read out as a number. All spectrochemical techniques that operate in the UV/visible and IR regions of the spectrum employ similar instrumentation; the only differences lie in the arrangement and type of sample introduction system, encoding systems, and information selection system.

3.1.1 Spectrometers

The optical information selector in Figure 7 sorts the desired optical signal from the many signals produced in the encoding process. Although it is possible to discriminate against background signals on the basis of time and position, most often discrimination is based on optical frequency (wavelength). The most widely used wavelength selection system is the monochromator, although there are a variety of other systems, including polychromators and spectrographs, and nondispersive systems like the Fabry-Perot, Michelson, Mach-Zender, and Sagnac interferometers. Our discussion will be limited to monochromators; for a thorough discussion of other types of wavelength selection systems, the reader is directed elsewhere.

Monochromators isolate one wavelength from the countless number of wavelengths found in polychromatic sources. A monochromator consists of two principal components: a dispersive element and an image transfer system. Light is transferred from an entrance slit to an exit slit by a series of mirrors and lenses; along the way it is dispersed into its various wavelengths by a grating (or sometimes a prism). To change wavelengths, one rotates the dispersive element; the result is that different wavelength bands are brought through the exit slit in succession. One can easily calculate the angular dispersion \( D_\alpha \) (i.e. the angular separation \( d\beta \)) corresponding to the wavelength separation \( d\lambda \) of a grating by knowing the angle of incidence, the angle of diffraction, the order of diffraction, and the groove spacing of the grating. For practical purposes, however, it is more important to calculate the linear dispersion, \( D_l = dx/d\lambda \) (a value that defines how far apart in distance two wavelengths are separated in the focal plane), or the reciprocal linear dispersion, \( R_l \) (the number of wavelength intervals contained in each interval distance along the focal plane).

A monochromator’s resolution is closely related to its dispersion in that dispersion determines how far apart two wavelengths are separated linearly while an instrument’s resolution determines whether the two
wavelengths can be distinguished. In many cases the resolution is determined by the monochromator’s spectral bandpass, s, defined as the half-width of the wavelength distribution passed by the exit slit. If the slit width is large enough to ignore aberrations and diffraction, a scan of two closely spaced monochromatic lines of peak wavelengths \( \lambda_1 \) and \( \lambda_2 \) will be just separated (baseline resolution) if \( \lambda_2 - \lambda_1 = 2s \). Therefore, the slit-width-limited resolution \( \Delta \lambda_s \) is given by Equation (3):

\[
\Delta \lambda_s = 2R_0 W
\]

where \( W \) is the slit width.\(^{51}\) By adjusting the monochromator so that \( \Delta \lambda_0 = \Delta \lambda_1 \) and \( W = \Delta \lambda / R_0 \), the image of \( \lambda_1 \) will be completely passed, while that of \( \lambda_2 \) will be at one side of the exit slit.\(^{51}\)

### 3.1.2 Detectors

Two detectors are used most often in atomic spectroscopy: photomultipliers (the most common) and multichannel detectors. A photomultiplier is a more sophisticated version of a vacuum phototube. A cascade of electron collisions with dynodes of increasing potential and the subsequent ejection of electrons from each dynode’s surface leads to the formation of an electrical current proportional to the number of photons striking the detector. The process begins with a photon striking a cathode made of a photoemissive material (e.g. alkali metal oxides, AgOCS, CsSb). If the energy of the photon is above some threshold value, an electron is ejected from the cathode. Only a certain fraction of the photons with energy greater than threshold produce photoelectrons with sufficient KE to escape the photocathode. This fraction is called the quantum efficiency and is the ratio of the number of photoelectrons ejected to the number of incident photons. After leaving the photocathode, a photoelectron strikes the first dynode of the multiplier; this causes the subsequent ejection of two to five secondary electrons which are in turn accelerated by an electric potential to a second dynode where they cause the release of two to five more electrons. This multiplication process continues until the electrons reach the last dynode and impinge on the anode. A modern photomultiplier tube might have 5–15 dynodes (made of a secondary emission material like MgO or GaP) in a cascade. The result of this photomultiplication is a large charge packet a few nanoseconds in width produced at the anode for each photoelectron collected by the first dynode. Photomultipliers can be operated in either analog mode, where the average current that results from the arrival of many anodic pulse is measured, or in photon counting mode, where the number of anodic pulses, and not photons, is counted per unit time.

A wide variety of photomultipliers is available with both end-on and side-on viewing for adaptation to a wide variety of monochromators. Care must be given to the wavelength range over which one is working to ensure a uniform response. Other concerns for the spectroscopist, all of which are beyond the scope of this article, include the quantum efficiency of the photomultiplier, the multiplication factor of each dynode, the operating (accelerating) voltages applied to the dynodes, and the dark current generated when a potential is applied between the anode and cathode, with no photons hitting the photocathode.

The second type of detector that is widely used in atomic spectroscopy is the multichannel detector. These devices include early photographic detectors like photographic film or plates, as well as modern detectors such as photodiode arrays and charge-coupled and charge-injection devices. The idea behind the multichannel detector is simultaneous detection of dispersed radiation. Modern multichannel detectors usually take the form of some sort of solid state pn-junction diode device packaged in integrated-circuit form with a large number (e.g. 256, 512, or 1024) of elements arranged in a linear fashion. These devices often have linear dynamic ranges of two to four orders of magnitude. Limitations at the low end result from the noise associated with readout of a given dynode. Limitations at the upper end are the result of saturation; this is determined by the number of electron–hole pairs that can be created. A typical saturation charge is 1–10 pC. The reader is referred to several excellent references for a more thorough description of multichannel detectors.\(^{52–54}\)

### 3.2 Atomic Emission Spectroscopy

AES is the simplest spectroscopic method for determining the elemental composition of a sample, and is the logical place to start talking about atomic spectrometry. Optical emission results from electron transitions occurring within the outer electron shells of atoms. These transitions give rise to line spectra where the wavelength of the lines relates to the energy difference of the levels according to Equation (4):

\[
\Delta E = \frac{hc}{\lambda}
\]

Spectroscopists often categorize spectral transitions according to term symbols. For a complete discussion of term symbols, the reader is referred elsewhere.\(^{55}\) A brief discussion follows.

Each electronic state of an atom has five quantum numbers that define its electronic configuration. These include the principal quantum number, \( n \), the orbital angular momentum quantum number, \( l \), the orbital
magnetic quantum number, \( m_s \), the electron spin quantum number, \( s \), and the spin magnetic quantum number, \( m_l \). According to Ingle and Crouch,\(^{51} \) for many-electron atoms, the hydrogen quantum numbers can be thought of as describing the individual electrons, but they are not “good” quantum numbers for the entire atom. Good quantum numbers are associated with operators that commute with the total atom Hamiltonian. These include the resultant orbital angular momentum quantum number, \( L \), produced by coupling the orbital angular momenta of each electron, and the resultant spin quantum number, \( S \). For atoms with weak spin–orbit interactions, \( L \) and \( S \) couple to produce a total angular momentum quantum number, \( J \). A multiplet of closely spaced states with the same \( L \) and \( S \) values but different \( J \) values is called a spectroscopic term, and is designated as \( n^{2S+1}L_J \), where \( n \) is the principal quantum number for the valence electrons, \( 2S + 1 \) defines the multiplicity, and \( J \) is the total angular momentum quantum number. Of all the possible transitions between states, only a fraction of them are observed. From quantum mechanical principles, it is possible to derive selection rules that tell which transitions are allowed (i.e. those that occur with high probability and give reasonably intense lines) and which are forbidden (i.e. those that occur with low probability and give weak lines); this is beyond the scope of this article. For this discussion it is sufficient to note that term symbols for almost all practical configurations have been tabulated\(^{55} \) and tables of spectral line intensities have been assembled for nearly all the elements.\(^{56} \)

In AES, the information relevant to an analysis can be found in the radiation emitted by excited analyte atoms decaying from a nonradiational activation event. The radiant power of this emission is a function of several factors, including the population density of the excited atoms, the number of photons emitted per second by each atom, the energy of each photon, and the volume of the emitting system. The reader is directed elsewhere for a more complete discussion of each of these factors.\(^{51} \)

AES has the power to provide rapid, qualitative, and quantitative multi-element analyses. Although a qualitative survey of the elements (i.e. a plot of the analytical signal versus wavelength) in a sample may be useful, more often the desired information is the concentration of an analyte. Unfortunately, this is almost never obtained directly as the result of an absolute measurement of an optical signal because amplitude and elemental concentration are seldom related in a simple way. Obtaining the desired concentration from an optical measurement usually involves calibration, subtraction of blanks, comparison with standards, and other similar procedures.\(^{51} \) Quantitative analysis of a single element is most easily accomplished in AES by monitoring the emission intensity as a function of the analyte’s concentration under a given set of conditions (e.g. constant discharge gas pressure, voltage, and current at a given wavelength). Standards, often provided by the National Institute of Standards and Technology, provide a range of concentrations over which a calibration curve can be developed. The signal intensity of an unknown concentration is then compared with the intensity of the standards, thus providing the concentration of the analyte in question.

Although simple in principle, quantification is complicated by a number of factors, including spectral background, incomplete wavelength separation, self-absorption, peak broadening, etc., most of which are beyond the scope of this article. When one considers these complicating issues, it is clear why it is important to control conditions precisely and use standards for the most accurate quantification.

Instrumentation used for emission spectroscopy includes an excitation source, a sample container, a wavelength selector, and a radiant power monitor. Depending upon the spectrochemical method, the excitation source and sample container may be separate components or they may be combined, as is the case with the GD. Figure 8 illustrates one instrumental configuration used in our laboratory at the Oak Ridge National Laboratory for AES. A 0.5-m monochromator serves as the wavelength selector and the combination of a photomultiplier tube, preamplifier, and readout photometer comprise the radiant power monitor. Figure 8 also illustrates three common sources used with GD emission spectroscopy – a planar cathode discharge and two versions of the hollow cathode discharge.

The planar cathode discharge is thus termed because the portion of the sample exposed to the discharge is flat. It is often contrasted with the coaxial or pin-type cathode used more commonly with mass spectrometry and described elsewhere in this chapter. With the development of the Grimm lamp in 1968\(^{57} \) and its eventual commercialization, the planar cathode discharge gained widespread use for emission spectroscopy. Although other planar cathode discharges have been developed in the past 30 years, the Grimm source still finds the greatest application today. One interesting feature of the Grimm source is that it is an obstructed discharge (i.e. the discharge is confined to the sample by the extension of the anode into the cathode dark space). Moreover, the vacuum in the anode–cathode inner space is lower than in the discharge region itself, necessitating a dual outlet pump with a larger throughput for the inner electrode space.\(^{58} \) Another interesting feature of the Grimm source is that the cathode is located outside of the source itself; this provides for easy sample interchange, and means that the Grimm source is particularly amenable to the analysis of any flat conducting surface that can be brought up to the source opening, such as metal sheets or disks.
Typical operating conditions for the Grimm source are 500–1000 V, 25–100 mA, and 1–5 Torr. The relatively high power produced by the source (12.5–100 W) means that the cathode is often water-cooled; this usually is not a problem in emission spectroscopy, but makes interfacing the Grimm source with a mass spectrometer (with its high vacuum requirements) more difficult.

Planar cathode discharges have been interfaced to a variety of commercial emission instruments. Grimm-type sources find their greatest use in trace elemental analysis of solids and in depth profiling of layered metal samples. Detection limits by emission spectroscopy are of the order of 0.1 ppm. Precision of the order of 0.5–5% has been obtained for concentrations in the 0.01–10 mg g\(^{-1}\) range. Ablation rates range from 0.1 to 3 mg min\(^{-1}\) depending upon the element, discharge area, current, and voltage. At these rates, the Grimm source cannot be used for thin film analysis, but it is ideal for thin layer analysis or in-depth profiling where it may be necessary to profile from a few nanometers to several tens of micrometers in a relatively short time. Recently, Hocquaux wrote an excellent chapter on thin film analysis by GD emission spectroscopy. The other two sources shown in Figure 8 are hollow cathode discharges. Although the hollow cathode discharge appears similar to the planar cathode physically, the shape of the cathode cavity provides some properties that make it appealing for atomic spectroscopy. This discharge derives its name from a cathode that has been drilled out to form a cylindrical cavity closed at one end. The so-called hollow cathode effect can be visualized as a GD with two parallel cathode plates being brought sufficiently close to each other until the two cathode glow regions coalesce. The result of this coalescence is an increase in current density that can be several orders of magnitude larger than a single planar cathode at the same cathode fall potential. Coupling this increase in current density with the longer residence time that the analyte experiences in the negative glow region (due to the cathode’s shape) results in a dramatic increase in the intensity of radiation emitted compared to a planar cathode. In addition, background intensities are low because electron number densities are low, resulting in a very high signal-to-background ratio. To perform an analysis using a hollow cathode discharge, it is necessary to machine the sample into the shape of a cylinder, or to place powder or metal chips into a hollow cathode made of some inert material such as graphite. One can also analyze solutions by drying a residue on the hollow cathode surface. Operating conditions vary widely, but typically range from 200 to 500 V, 10 to 100 mA, and 0.1 to 10.0 Torr. Detection limits have been reported in
the picogram range, but more typical results are in the nanogram range. Although hollow cathode discharges are used widely in atomic spectroscopy, the majority of these devices are light sources for AAS (see below). A typical hollow cathode lamp (HCL) is depicted at the extreme bottom right of Figure 8.

3.3 Atomic Absorption Spectroscopy

In absorption spectroscopy, spectrochemical information can be found in the magnitude of the radiant power from an external light source that is absorbed by an analyte. To obtain information relevant to measuring an element’s concentration, however, it is necessary for the frequency of the incident radiation to correspond to the energy difference between two electronic states of the analyte atoms being measured. Often, but not always, the atoms start in their electronic ground state and are excited to a higher lying electronic state by the incident radiation. The adsorption of this radiation usually follows Equation (5):

$$A = -\log T = -\log \frac{\Phi}{\Phi_0} = abc$$

where $A$ is the absorbance, $T$ is the transmittance, $a$ is the absorptivity, $b$ is the path length of absorption, and $c$ is the concentration of the absorbing species. This equation is commonly referred to as Beer’s law. To calculate the concentration, one measures the incident radiation ($M_0$) and the transmitted radiation ($M$), calculates the absorbance, and relates the absorbance to concentration using a series of standards and calibration curves, similar to emission spectroscopy.

A typical instrumental configuration for an atomic absorption spectrometer is shown in Figure 9. A hollow cathode, fabricated from the elements of interest, is often used as the source of incident radiation, although an electrodeless discharge lamp may be used for some elements such as As, Se, or Te, where the emission from an HCL may be low. The HCL is focused to a point inside the discharge and then refocused into the entrance aperture of the monochromator. To obtain the background signal, one can use a shutter, or alternatively modulate the HCL and measure the background during the off period. In the arrangement shown in Figure 9, a mechanical chopper is used to facilitate background subtraction by providing a reference signal to a lock-in amplifier. Transmission is

**Figure 9** Schematic of an instrumental arrangement used at the Oak Ridge National Laboratory for AAS. (Reproduced by permission from Gough. Copyright (1976) American Chemical Society.)
measured first with the discharge off and then with the discharge on, often for a range of currents and voltages. Using Beer’s law, absorbance is calculated for a series of standards to produce a calibration curve; the absorbance of an unknown is then correlated with its concentration.

Two different discharge configurations are shown in Figure 9 for atomic absorption. The one on the left is an atomic absorption sputtering chamber developed by Gough. A planar cathode is mounted near the top by pressing the sample against an O-ring that provides the vacuum seal. The gas flow of the cell was designed to provide transport of sputtered atoms into the observation zone, 1–2 cm from the sample. In 1987 Bernhard took the idea of gas-assisted transport of atoms one step further, reporting on a design that used gas jets aimed at the sputtering surface to increase significantly the sampling rate as well as the absorption signal in a sputtering chamber. A commercial atomic absorption cell was designed based on this principle (Atomsource, Analyte Corporation, Medford, OR), renewing the interest in AAS that began with Walsh more than four decades ago. The source on the right is a much simpler atom generator. It is based on the direct insertion probe (DIP) design of King. The coaxial cathode in King’s original design has been replaced by a stainless steel ring that accommodates a demountable hollow cathode (4.82 mm in diameter × 2.54 mm in length with a 3.18-mm hole in the center). The DIP facilitates alignment of the HCL emission, which is focused through the orifice (i.e. the region of highest atom density) and collected after it passes through a window in a six-way vacuum cross. Typical operating conditions for this source are 1.0–3.0 Torr, 500–2000 V, and 2–15 mA. Detection limits for GD atomic absorption are in the low parts per million range. Although GD atomic absorption is not as widely used as flame or graphite furnace atomic absorption, it has found its niche in applications where analysis by other atomic absorption methods (primarily solution-based) are difficult (e.g. the analysis of materials that are difficult to dissolve).

3.4 Atomic Fluorescence Spectroscopy

Atomic fluorescence is similar to AAS in that both rely on an external light source to produce an analytical signal from an atomic vapor. In fluorescence spectroscopy, the signal is contained in the emission of photons from the atom population after absorption of the incident energy. There are five basic types of fluorescence: resonance, direct-line, step-wise, sensitized, and multiphoton fluorescence. For this discussion, it is not important to define these five types, only to say that the differences lie in the excitation and relaxation pathways that each follow to produce fluorescence. Resonance fluorescence (where the same upper and lower levels are involved in the excitation–de-excitation process so absorption and emission wavelengths are the same) finds the most widespread use in analytical spectroscopy because the transition probabilities and the source radiances are the greatest for resonance fluorescence when conventional line sources are used.

Figure 10 shows a conventional instrumental arrangement for a single-beam atomic fluorescence spectrometer. Radiation from the source is focused into the GD. Fluorescence photons are imaged onto the entrance aperture of a monochromator that isolates the analyte fluorescence from background emission and fluorescence from other species. Fluorescence is usually viewed at an angle of 90° with respect to the excitation source to minimize the collection of scattered source radiation.

One critical component of an atomic fluorescence spectrometer is the excitation source. HCLs, electrodeless discharge lamps, and metal vapor discharge lamps have all been used successfully, although today most fluorescence experiments use a laser. Lasers are superior sources for atomic fluorescence because they provide a fluence several orders of magnitude greater than other sources, are tunable over a wide wavelength range, have spectral bandwidths much narrower than absorption line widths, and can be focused to very small spot sizes. Both continuous wave (with chopping) and pulsed lasers have been used, with dye lasers finding the most use because they can be tuned over a large number of wavelengths. An inductively coupled plasma has also been used as an excitation source; here, the excitation wavelength is governed by the analyte that is aspirated into the torch (usually at high concentrations).

Like AES and AAS, the ideal atomizer for fluorescence would produce a stable population of atoms of sufficient number density to make quantification of small concentrations practical. A fluorescence atomizer should also produce minimum thermal excitation to limit analyte and interference emission, a potential source of background. When this stipulation is met, Rayleigh scattering from atoms or molecules determines the fundamental limitation for background noise.

Most atomic fluorescence measurements have been made with flame atomizers, but recently inductively coupled plasma has been used. Plasmas generally provide better atomization efficiency and a larger population of free atoms than flames. When analyzing a solid sample, however, an atomizer, like the one shown in Figure 10, is more practical. This simple design consists of a Pyrex glass housing into which a 6.35-mm diameter sample rod is inserted through a ceramic sleeve and sealed to the cell with O-rings. Quartz windows are glued into the cell to allow a laser beam to pass. A fill port and an evacuation port are also provided, and the entire
cell is pumped by a single rotary vacuum pump. A DC power supply (Electronic Measurements, Eatontown, NJ) provides voltages up to 600 V and currents up to 200 mA. A typical operating voltage is 570 V at 25 mA. The cell is pressurized with argon to between 900 and 1000 Pa (7–8 Torr).

More recent applications of atomic fluorescence by this group have produced GD cells constructed from high vacuum components like ConFlat® crosses and flanges with sapphire windows, but the principles of operation remain the same – fluorescence is detected 90° to the laser beam path by a photomultiplier tube. The fluorescence signal is amplified by a wideband amplifier and processed by a gated integrator and boxcar averager; the result is a fluorescence spectrum as a function of wavelength which is indicative of those elements in a GD cathode for which a fluorescence transition is allowed.

3.5 Optogalvanic Spectroscopy

The final optical technique to be discussed is optogalvanic spectroscopy. The optogalvanic effect was first observed using a weak, incoherent light source in 1928; light from one neon discharge affected the electrical characteristics of a nearby discharge. The process is quite simple; in a discharge there is an equilibrium established between the neutral species and the corresponding ions. If some means of energy is added to the discharge, the equilibrium position can be displaced and the fraction of ions altered; this is the case when a photon is absorbed by the gaseous atom or molecule. This permits one to measure optical absorption by an all-electronic means, that is, without the use of photodetectors. The electrical circuit employed to monitor the optogalvanic effect commonly includes a ballast resistor in series with the discharge resistance; the discharge impedance change is usually monitored as a change in the discharge voltage. The light source is modulated, and a lock-in amplifier is employed to measure the alternating current component of the discharge voltage induced by absorption of light as the source wavelength is scanned. In theory, the atomization source could be any of the discharges discussed thus far; in practice, however, we have found that the demountable hollow cathode operating in the same fashion as it does for atomic absorption provides the greatest flexibility for optogalvanic spectroscopy.

4 MASS SPECTROMETRIC METHODS OF ANALYSIS

Much like the spectrochemical techniques described above, mass spectrometry offers the analyst a method for determining the identity and quantity of a particular species in a sample. This technique however, provides

---

**Figure 10** Schematic of a conventional instrumental arrangement for a single-beam atomic fluorescence spectrometer.
analytical information through the separation and subsequent detection of charged species associated with the sample. Ions are generated in the source region and selected by mass-to-charge ratio \( \frac{m}{z} \) usually using electrostatic or magnetic fields.

In this section, the basic requirements necessary to obtain mass abundance information are described, along with five types of mass spectrometers: quadrupole mass filters, magnetic sector mass analyzers, QITs, FTICR devices, and TOF mass spectrometers. These reviews will focus only on variants that have been coupled to the GD source. Table 4 provides basic information and characteristics that are unique to each of the mass spectrometric systems.

4.1 Basic Requirements Necessary to Obtain Mass Abundance Information

Mass spectrometric systems in general require a number of fundamental components to create, transport, separate, and detect ions, manipulate the resulting signal to account for system inconsistencies, and provide useful information to the analyst (see Figure 11). A number of these components will be considered in the following section.

4.1.1 Ion Source

There are a number of GD source geometries that can be implemented for a variety of analyses (see Table 1). Some types were designed, and are well suited, for optical applications as outlined in the previous section. Many of the advantages afforded by the optically applicable sources stem from an the enhancement of the atom population, often a result of increased sputtering rate or a confined viewing region that facilitates optical viewing. Mass spectrometry requires a different set of criteria, however. Sources designed for mass spectrometric applications must provide a reasonable population of analyte ions (not atoms). These ions then must be extracted from the source region into the mass analyzer. For these reasons, one appropriate source for mass spectrometry is the coaxial cathode. Ions generated by the coaxial cathode are extracted through an ion exit orifice in the anode. Ionization is dominated by the Penning process that leads to an ion population with a narrow KE spread relative to other GD source geometries. \(^{(72)}\) This geometry also facilitates sample introduction via a DIP, making trivial the appropriate adjustment of the plasma relative to the ion exit orifice.

![Figure 11](image.png) Block diagram of typical GD mass spectrometer system components.
4.1.2 Vacuum Systems

Mass spectrometric techniques impose stringent requirements on a vacuum system. One advantage of interfacing any of the currently available mass analyzers to the GD as compared to an atmospheric pressure source arises from the operating pressure of the ion source itself. Most mass spectrometers operate at pressures from 10^{-5} to 10^{-9} Torr. The GD source also operates at a reduced pressure (0.1–10 Torr with support gas), although not nearly as low as those required for mass analysis. The pressure differences associated with GD mass spectrometric implementation are overcome using differential pumping schemes. These types of systems employ a series of pumping regions to reduce the effect of the required pressure drop. A typical scheme would involve pumping the ion source with a rotary-vane roughing pump. This would evacuate the discharge cell to a pressure of approximately 10^{-3} Torr in the absence of discharge gas. The next differentially pumped region facilitates extraction of ions from the ion source. This region is often evacuated using a turbo molecular pump or oil diffusion pump and maintains pressures of 10^{-4}–10^{-5} Torr during discharge operation. The analyzer region, which includes the mass separation components as well as the detector, is evacuated using a turbo molecular, oil diffusion, cryo, or ion pump and maintains pressures of 10^{-7}–10^{-9} Torr.

4.1.3 Ion Optics

Ions generated in the GD plasma must be transported efficiently and indiscriminantly to the mass separation region to facilitate accurate and precise analytical measurements. The transfer of ions from the source to the mass analyzer is usually accomplished using an optics system. One type of system used for ion transport is the Einzel lens.\(^{(12,73,74)}\) This type of lens is based on three conducting tubular lenses of similar dimension mounted in series. Typically, similar potentials are placed on the first and third lenses while that of the middle lens is adjustable. Many times the middle lens is held at ground potential. As an ion beam passes through this lens system it is focused in a manner analogous to an optical beam, reaching a focal point on the opposite side. It is important to note that cylindrical lens systems like the Einzel lenses produce a cylindrical ion beam rather than a planar one. This characteristic may limit their use for some applications such as ion guides for magnetic sector instruments which require a ribbon-shaped ion beam.

A second type of ion optic is the Bessel box.\(^{(75,76)}\) This technology is used in conjunction with QMAs to remove photons and neutral species from the ion beam while simultaneously limiting the KE spread of ions entering the quadrupole lens region. If the energy spread is too great quadrupole performance deteriorates, resulting in degradation of mass resolution, peak splitting, and asymmetrical peak shapes.\(^{(77,78)}\) A Bessel box is constructed from a square entrance and exit electrode surrounded by sets of electrodes on each of the other four sides. A center plate or cone is located within the box parallel to the entrance and exit electrodes. Potentials are applied to each electrode. These potentials can be varied to permit the transmission of ions with a discrete KE. Photons and neutral species will not be affected by these potentials and will proceed into the box linearly and collide with the center stop, removing them from the beam. Ions entering the box with too little KE will be repelled toward the entrance plate. If the energy of the ion is too great it will not be steered around the center stop and will collide with the side electrode or exit plate. Only ions with the selected KE will travel around the center stop, through the exit aperture and into the quadrupole region. In most cases, one or two lenses are located behind the exit aperture to focus and transport the selected ions.

Quadrupole lenses can also be used as ion guides when operated in an RF-only mode.\(^{(79,80)}\) It will be shown later in this chapter that the application of both DC and RF potentials provides a notch filter that can be adjusted and scanned to provide mass unit resolution. When only an RF potential is applied, the quadrupole acts as an ion guide, focusing all ions through quadrupole lenses.

4.1.4 Detection Systems

Three types of detection systems are routinely used for GD mass spectrometric measurements: Faraday cups, electron multipliers, and microchannel plates (MCPs). Detector selection is often independent of the mass analyzer in use.

The detector used most often for applications with high ion abundance is the Faraday cup. Modern Faraday detectors are extremely quiet. When operated using high grade resistors and amplification components, these detection systems offer state-of-the-art measurements with respect to signal-to-noise ratio. Although not currently available on commercial GD mass spectrometric systems, recent developments in multi-Faraday array detection systems offer increasingly precise measurements for scanning instruments by negating the effects of source fluctuations on measurements. Each Faraday cup in the array is dedicated and positioned to measure a single isotope at a given dispersion setting. This allows simultaneous collection of the selected ions during the acquisition sequence without scanning the mass dispersion device, virtually removing any dependence on fluctuations in ion beam intensity arising in the source. Minimization
of source fluctuation effects afforded by multicollector arrays is most important for applications involving the measurement of isotope ratios.

For applications requiring optimum sensitivity, discrete dynode electron multipliers operated in a pulse counting mode are required. Operation in this mode registers a signal pulse for every ion impinging on the first dynode. Each impinging ion generates a number of secondary electrons that are successively amplified by each dynode. Overall gains of $10^6$–$10^8$ are common when using multipliers with 14–20 dynodes. After the pulse of electrons leaves the multiplier, it is amplified and proceeds to a discriminator that is set to remove pulses arising from dark noise. The signal is then sent to a universal counter that records each pulse, stores it for a given time, and passes it to a computer-based data acquisition system that presents the data in a usable form. It is important to keep the count rate low enough ($<10^6$ counts s$^{-1}$) to maintain the integrity of the pulse-counting system and to ensure that any pulses, not measured because of time lag in the electronics, will be statistically insignificant.

Daly detection systems behave in a manner similar to electron multipliers. In the Daly system, the ion beam is accelerated to 10–20 kV and directed onto a highly polished aluminized steel electrode positioned directly behind the collector slit. Approximately eight electrons are liberated from the aluminized surface for every impinging ion. These electrons are repelled by the high negative potential applied to the electrode and directed onto a scintillator that produces a photon for each electron. These photons are counted by a photomultiplier located outside of the vacuum system. The resulting pulses are treated in a fashion analogous to that of the electron multiplier. Both Daly and electron multiplier-based detection systems can be operated in a mode that integrates the current of the impinging ion beam. This mode of operation is used for applications that do not impose such stringent sensitivity requirements.

A third detection system is used most often with TOF instruments and is built around an MCP detector. The MCP is characterized by a large, flat active area, high gain, and excellent time response. These operating parameters make it an ideal detector for TOF mass spectrometry. These detectors are fabricated from very thin glass wafers or plates perforated with microscopic channels oriented parallel to the impinging ion beam. The nature of the detector material is such that, in the presence of a potential bias (up to 1200 V), an ion impinging on the entrance to one of the channels will liberate one or more electrons which will, in turn, cascade through the channel, liberating further electrons with each wall collision. Amplification of the order of $10^4$ is routinely realized for a single MCP. After emerging from the MCP, these electrons are collected by a positively charged electrode positioned parallel to the MCP. The resulting signal is further amplified and manipulated using a fast digitizing oscilloscope or any number of computer-based flash analog-to-digital converter (ADC) computer boards. Two or more MCPs can be arranged in a stack orientation to amplify further the signal thus increasing system performance.

### 4.2 Magnetic Sector Mass Analyzers

Initially used by Aston for his studies of gaseous discharges, the magnetic sector mass analyzer, or mass spectrograph as Aston called it, is based on the spatial dispersion of ions with different $m/z$ that is effected when they traverse an electromagnetic field. The magnetic field acts as a prism dispersing monoenergetic ions of differing $m/z$ values across a focal plane; see Figure 12(a). The radius of the curved flight path of an ion through a magnetic field is given by Equation (6):

$$r_m = \frac{144}{B} \left( \frac{mV}{z} \right)^{1/2}$$

(a) Magnetic Sector Mass Spectrometer

(b) Quadrupole Mass Spectrometer

Figure 12 Schematic of (a) a magnetic sector mass spectrometer and (b) a QMA.
where $B$ is the magnetic field strength in gauss, $m$ is the atomic mass of the ions in amu, $V$ is the acceleration voltage of the ion prior to entrance into the magnetic field in volts, $z$ is the charge of the ion, and 144 is a constant prescribed by the units.\(^{(83)}\) Because a sector instrument can be made to focus ions onto a plane, it can be designed as either a single or multi-collector instrument. A single electronic detector is used when operating in the sequential acquisition mode. Different $m/z$ ions are brought into focus on the detector by varying either $B$ or $V$. Simultaneous acquisition instruments utilize either a photographic plate or a detector array oriented in the focal plane. These systems allow the detection of a suite of different $m/z$ ions at a given $B$ and $V$ setting. Although more expensive, the array-based systems offer shorter analysis times and the potential for more precise measurements because source fluctuation effects are minimized.

Mass resolution is another parameter that influences the ability of a system to solve an analytical problem. Mass resolution is a measure of the instrument’s ability to separate ions having small mass differences. Mass resolution in magnetic sector instruments is defined by ion beam focusing in the focal plane. Single-focusing instruments rely on direction focusing to increase resolution. This is accomplished by narrowing the entrance and exit slit widths, thus reducing the width of the ion beam.\(^{(85)}\) Mass resolution becomes more important when ions of the same nominal mass must be separated.

Multi-sector instruments are quite complex and expensive to build and maintain. They provide adequate to excellent resolving power, especially when an electrostatic sector is coupled to a magnetic sector to provide double (momentum and energy) focusing. When operated in the sequential detection mode, sector instruments are hindered by relatively slow scanning speeds which adversely affect analysis time and sample throughput. In the past, a number of commercial instruments were available from a variety of vendors based on the sector design. Currently, however, their availability has become somewhat limited.

### 4.3 Quadrupole Mass Filters

Since its development in the 1950s and early 1960s, the quadrupole mass spectrometer has become a powerful tool for the analysis of a variety of materials. Much of its popularity stems from the time of its development when it was viewed as a more rugged, more compact, and more cost-effective alternative to magnetic sector mass spectrometry systems, albeit with compromised performance. The quadrupole mass filter is a variable bandpass filtering ion optic, analogous to an optical bandpass filter. The quadrupole system is capable of transmission of all ions when operated in the RF-only mode (as described earlier), or of measuring only one $m/z$ at a time as a sequential mass analyzer. The quadrupole offers the ability to scan the entire mass range very rapidly or to “peak-hop” among a series of selected isotopes.\(^{(84)}\)

A quadrupole mass filter consists of four high precision, cylindrical, conducting rods or poles arranged in a square configuration, as shown in Figure 12(b). Mass filtering is accomplished by applying steady state DC and pulsed RF potentials to these poles. The application of these voltages results in the formation of hyperbolic electric fields, with the ideal quadrupole defined by Equation (7):

$$\frac{r}{r_0} = \frac{1.148}{7}$$

where $r$ is the radius of each rod and $r_0$ is the radius enclosed by the electrodes.\(^{(85)}\) The effects that the applied potentials and resulting electric fields have on a charged particle are best described by the ion trajectory in the $x-z$ and $y-z$ planes. The set of poles in the $x-z$ plane have a positive, time-independent DC voltage and a time-dependent RF voltage applied to them. The poles in the $y-z$ plane have a negative, time-independent DC voltage and a time-dependent RF voltage applied to them. The RF potential applied in the $y-z$ plane is 180° out of phase with the RF voltage in the $x-z$ plane. Ions enter and travel between the poles along the $z$-axis.

In the $x-z$ plane, larger mass ions are focused along the $z$-axis by the positively biased DC field, while the smaller mass ions are destabilized by the RF field. In the $y-z$ plane, larger mass ions are deflected away from the $z$-axis by the negatively biased potential while ions of smaller masses are stabilized by the RF field. The net result is a high-pass filter in the $x-z$ plane and a low-pass filter in the $y-z$ plane, allowing the stabilization and transmission of ions above a selected $m/z$, and the stabilization and transmission of ions below a selected $m/z$, respectively. When these two types of filters coexist, a narrow bandpass mass filter results. The magnitude of the DC potential and the frequency of the RF potential can be varied to allow transmission of different $m/z$ ions through the quadrupole lenses, thus providing a means of $m/z$ selection.

Quadrupole-based GD systems have been used extensively.\(^{(28,30)}\) The relatively low cost and robustness of these instruments have made them an excellent choice for both the researcher and routine sample analyst. A major limitation of the quadrupole system is its relatively low resolving power, significantly increasing the deleterious effects of overlapping polyatomic interferences. Appropriate selection of operating conditions and discharge gas can minimize some of these concerns, but performance of quadrupoles does not match that of sector-based instruments.
4.4 Ion Trap and Fourier Transform Ion Cyclotron Resonance Devices

While sector and QMAs were being developed for elemental and isotopic applications, the QIT technology was being driven by needs in the organic community. FTICR mass spectrometry, another form of ion trapping technology, has filled a niche in the biological mass spectrometry community because of its unrivaled mass resolution.\(^{(86)}\) Recently, these devices have been characterized and used by the inorganic mass spectrometric community. A number of external ionization sources have been implemented, including the GD.\(^{(86,87)}\) This section will describe the operating principles of both the QIT and FTICR systems and cover some of their unique properties.

The operation of the QIT is very similar to that of the quadrupole mass filter. Two of the opposing rods in the quadrupole mass filter are connected to form a ring, and each of the remaining pair of rods is replaced by a hyperbolic endcap, as shown in Figure 13(a). The result is a three-dimensional quadrupole field that is symmetric with respect to rotation about the center. The end caps are oriented along the former z-axis, and the x- and y-axes become a plane, r, symmetric about z. In the most common inorganic applications, externally generated ions are collected and stored within the trap. Typically the internal pressure of the QIT is \(10^{-3} - 10^{-4}\) Torr He. Helium is introduced to cool collisionally the precessing ions, thus allowing them to relax toward the center of the trap and increase trapping efficiency.

Stored ions precess with a frequency that is \(m/z\) dependent. Ions that are stored in the trapping fields have a fundamental secular frequency along the axial or z-axis. When a supplemental AC signal is applied to the end-cap electrodes, ions whose secular frequencies are in resonance with the applied frequency are excited to higher translational energies. The magnitude of this resonance excitation is directly proportional to the amplitude of the applied signal. At appropriately high amplitudes, the ions can either be lost in collisions with an electrode or ejected through apertures in the exit end-cap electrode. Mass analysis can thus be performed by scanning the frequency of the AC excitation signal. During a scan, ions become destabilized through the excitation process and are selectively ejected through the exit end-cap electrode and are then detected using an electron multiplier.

The relatively high operating pressure of the QIT makes it well suited for coupling to ion sources that operate at higher pressures, such as the GD. Ions from the GD can be directly introduced into the QIT without the need for an elaborate differential pumping scheme. The high pressure and trapping nature of the QIT also facilitate the use of ion–molecule interactions to provide a number of advantageous results, most notably the suppression of unwanted contributions from isobaric interferences.

The FTICR mass spectrometer was initially considered by the elemental mass spectrometry community for its high resolving power. This characteristic allows the physical separation of the analyte signal from interferences without actually removing the interfering species from the cell. High resolution does not come without a cost, however; FTICR systems are one of the most expensive types of mass spectrometers available. The basic operation of the FTICR system is similar to that of the QIT. Precessing ions are constrained spatially within a cubic cell using both electric and magnetic fields. A homogeneous magnetic field confines ions radially, while electrostatic potentials are applied to the end-caps of the cell to trap the ions axially; see Figure 13(b). Ions trapped by these fields are characterized by three motions: one that confines the ions between the two end-cap electrodes, magnetron motion, and cyclotron motion.\(^{(88)}\) The ions orbit perpendicular to the applied magnetic field at the ion characteristic cyclotron frequencies, \(T_c\), that are inversely proportional to their \(m/z\) values and proportional to the magnetic field strength, \(B\).\(^{(89)}\) as shown

---

**Figure 13** Schematic of (a) a QIT mass spectrometer and (b) an FTICR mass spectrometer.
Ions are excited to larger cyclotron orbits by the application of a resonant RF potential to transmitter plates. An image current is generated as the coherent ion packets of a given \( m/z \) come into close proximity to the receiver electrodes. This current is converted to a voltage, amplified, digitized, and stored as a transient signal. The Fourier transform converts these transient signals into their frequency components, \( T_c \), which are, in turn, related to the \( m/z \) as shown in Equation (8). Extremely high mass resolution can be achieved because the basis for mass measurement lies in measuring frequency, which can be done with great precision. It should also be noted that mass resolving power is inversely proportional to the ion \( m/z \), a fortunate circumstance for elemental analysis because all masses of interest are below 250 Da.

### 4.5 Time-of-flight Mass Spectrometers

Perhaps the simplest type of mass spectrometer, the TOF mass spectrometer, is depicted in Figure 14. Its operation is based on the KE equation, where KE is a function of mass, \( m \), and velocity, \( v \); alternatively it can be expressed in terms of charge, \( z \), and accelerating potential, \( V \), as shown in Equation (9):

\[
\text{KE} = \frac{1}{2}mv^2 = \frac{1}{2}zV
\]  

(9)

From this equation one can deduce that ions of different \( m/z \) accelerated to a common KE will have different velocities. The TOF instrument operates on the principle that if all ions leave the extraction grid at the same point in space and time with equal KEs, they will travel with different velocities, \( v_y \), that are inversely proportional to their respective masses, \( m_y \), as shown in Equation (10):

\[
v_y = \left( \frac{2\text{KE}}{m_y} \right)^{1/2}
\]  

(10)

The time needed to traverse the flight path distance \( D \) and to arrive at the detector is related to the \( m_y/z \) ion by Equation (11):

\[
t_y = D \left( \frac{m_y}{2zV} \right)^{1/2}
\]  

(11)

Monitoring the current at the detector (often an MCP) yields a time-dependent signal that can be correlated to the \( m/z \) using Equation (11). Mass resolution is determined directly from the temporal resolution \( \Delta t/t \), which is determined by the initial KE spread of the ions and the speed of the detection electronics.

The effects of this spread in initial energy can be minimized by using a reflectron TOF mass spectrometric instrument. This instrument geometry has a series of electrostatic lenses located at the end of the flight tube. Positive potentials applied to these lenses increase toward the detection end of the flight tube. Ions traveling down the flight tube enter this potential gradient and penetrate, slowing until they reach a point in the gradient equal to their initial KE. They are then accelerated in the opposite direction, traversing the flight tube a second time. They are then detected by an MCP located at the base of the flight tube. Ions of higher KE penetrate further into the reflectron field, increasing their flight distance (time) and effectively minimizing the impact on mass resolution.

TOF instruments are ideally suited for pulsed ion sources such as lasers or pulsed ion beam sputtering. SIMS using TOF technology has gained wide acceptance as a technique for the characterization of a wide variety of materials. TOF mass spectrometry is also well suited for use with the pulsed GD source. Although no commercial GD TOF mass spectrometric systems are
currently available, a number are being used for research activities.\(^{(37,38)}\)

5 CONCLUSIONS

Optical and mass spectrometric techniques using GD ion sources are now established as routine methods for the direct analysis of solid samples of widely different origin and composition. This article has focused on the fundamental operation of the GD source in a number of operating modes as well as the optical and mass spectrometric instrumentation used for elemental determination. These source–instrument combinations will undoubtedly continue to offer advantages essential for specific applications in the future.

REFERENCES

75. B.L. Bentz, PhD Dissertation, University of Virginia, 1980.
Graphite furnace atomic absorption spectrometry (GFAAS) is an atomic spectroscopic technique in which a small sample is placed inside a graphite tube that is then resistively heated to accomplish sample desolvation (for liquid samples), ashing or charring (to decompose the sample and volatilize some of the matrix) and finally atomization. The light from a line source characteristic of the element being determined is passed longitudinally through the tube and the absorbance resulting from the presence of free analyte atoms in the gas phase is measured. The signal is transient in character, lasting approximately 1–5 s, and the area under this transient peak is generally used in the construction of a calibration curve. Modern instrumentation provides high levels of automation with capabilities of background correction as well as routine methods of sample analysis, for example quality assurance/quality control (QA/QC), standard additions, matrix modification, etc. Since the technique was first introduced in 1969, a lot of progress has been made in understanding the processes occurring within the graphite tube atomizer that ultimately produces the absorbance signal. An understanding of the free atoms formation process has facilitated the application of the technique to the analysis of a variety of complex samples.

Graphite furnace (also known as an electrothermal atomizer or ETA) atomic absorption (AA) is generally considered an ultratrace and microtrace analytical technique with limits of detection (LODs) in the low picogram range, precision of a few percent (relative standard deviation) and a dynamic range of about three orders of magnitude. In addition to its excellent sensitivity, it is unique in its ability to handle microsamples including aqueous solutions, viscous liquids, slurries and even solids. In general, there is considerable literature detailing methods and procedures for the determination of a variety of analytes in complex matrices that can be used by the analyst to apply the approach to new, complex analytical needs. When used correctly, this analytical tool can provide precise, accurate analysis for a wide range of sample types.

1 INTRODUCTION AND OVERVIEW

What is commonly referred to as GFAAS has been referred to as flameless AA in the past and is officially designated by IUPAC as electrothermal atomic absorption spectrometry (ETAAS). Typically, a commercial ETA consists of a graphite tube approximately 2.5–3 cm in length and 4–6 mm inside diameter. There is a small (1–2 mm diameter) hole in the center of the tube for introducing the sample, which is generally a solution aliquot of up to ca. 50 µL and is more typically 20–25 µL. Figure 1 shows a simplified schematic of the furnace and some of its typical operating features. Commercial tube furnaces are ca. 2.5 cm long and 0.6 cm in diameter and are composed of graphite with a relatively impervious pyrographite coating. The tube is resistively heated by an external supply and is protected from oxidation by a flow of sheath gas (typically Ar) around the furnace (not shown in Figure 1). The light source passes through the furnace and Beer–Lambert’s law relates the absorbance to the concentration. Shown in the graphical inserts are the temperature (heating) program of the
furnace and the absorbance signal that results once the “atomization cycle” is reached. As can be seen, the signal is transient in character and can last up to several seconds.

2 BRIEF HISTORY

The ability of free atoms in the gas phase to absorb characteristic wavelengths of light is not a new concept. In fact, the absence of discrete wavelengths in the yellow region of the solar spectrum was attributed to the absorption of these wavelengths by sodium as early as 1860 by Kirchoff. Walsh\(^1\) is credited with the first practical employment of AA spectrometry as a quantitative analytical tool using a flame as the “atomic cell” where free gaseous atoms are produced. Light from a forerunner of today’s hollow cathode lamp (HCL) was passed through the flame, the correct wavelength of radiation was isolated and detected. The attenuation of the light was then used for determining the concentration of analyte in the sample solution.

Prior to Wash’s publication, a large, heated graphite tube (“King furnace”) had been used for basic studies of the absorption characteristics of free atoms and molecules which were produced continuously from a large amount of material located within the furnace.\(^2\) However, there was no attempt to use this for quantitative or trace analysis, and there was no suggestion that this might even be possible.

L’vov\(^3\) was the first to combine the concepts of Walsh with a significantly altered version of the King furnace to demonstrate that quantitative analysis by AA could be conducted on discrete sample amounts by pulsed vaporization of the sample. Figure 2 shows a picture of this first graphite furnace atomizer for spectrochemical analysis by AA. This approach not only provided quantitative results but gave significantly improved sensitivities with LODs in the picogram range for many elements because of the significantly longer

---

**Figure 1** Conceptual diagram of a tubular ETA or graphite furnace atomizer. The atomizer is connected to a variable voltage power source and is resistively heated by current passing through the electrothermal vaporizer. Shown are the three basic heating regimes: dry, char and atomization cycles. The light source is passed through the tube and during the high temperature “atomization cycle” the analyte is vaporized and atomized. As a consequence an absorbance signal is registered.
sublimation temperature, and oxidizing to form a surface
the most readily apparent were its advantage of being
material of choice for a number of reasons, although
slowly and continuously distilled from the atomizer with
solid solutions that produced memory effects as they were
of metals that dissolved in the metal atomizer or formed
temperatures. However, there were also a large number
metal atomizers permitted complete vaporization at lower
currents) to bring about rapid heating. For analytes that
tended to form refractory carbides on graphite, these
were evaluated. The metals often provided the advantage
of higher resistance and lower mass, thereby permitting
lower powers and the use of higher voltages (with lower
currents) to bring about rapid heating. For analytes that
tended to form refractory carbides on graphite, these
metal atomizers permitted complete vaporization at lower
temperatures. However, there were also a large number
of metals that dissolved in the metal atomizer or formed
solid solutions that produced memory effects as they were
slowly and continuously distilled from the atomizer with
each subsequent firing. Graphite probably remained
the material of choice for a number of reasons, although
the most readily apparent were its advantage of being
available at high purity, having a very high (ca. 3400 K)
sublimation temperature, and oxidizing to form a surface
“oxide” (C–O_ads) that was readily removed as CO_(g)
and CO_(2(g)) from the surface with simple heating. The size
of the tubular atomizers ranged from very small devices
that heated very rapidly and could only accommodate a
few microliters of sample, to the “Woodriff furnace”(4,5)
which approached 25 cm in length and was preheated
before the sample was introduced.

Significant among the developments was Massmann’s(6)
early design of a directly heated tube into which the
sample was introduced. This design precluded the striking
of an auxiliary arc as was required with the L’vov design.
Most modern furnaces are smaller versions of this design
with tube lengths typically ca. 2.5–3 cm with a 4–7 mm
inner diameter (Figure 3). As shown in Figure 3, the
furnace is heated from the ends (i.e. “end-heated”) by
direct passage of current through the furnace.

With the tube furnace, it became readily apparent that
analyte elements were often “stuck” near the ends of the
tube since the tube did not heat uniformly. Greater
heat loss was experienced where the ends of the furnace
contacted the water-cooled endcones and could result in
a temperature gradient as large as 1000 K between tube
center and end.(7) The heating of the furnace was more
uniform during a rapid deposition of energy into it (e.g.
during a rapid thermal ramp) and the ends tended to
cool as heating rates decreased or once a steady state
temperature in the tube center was achieved. This often
resulted in material vaporizing from the initial deposition
site and recondensing on the now cooler ends of the
furnace. As a result, the next heating of the atomizer
produced a secondary release of these condensed metals,
giving rise to memory effects. This was not uncommon,
especially for the more refractory analyte elements. To
minimize this problem, it was common to use higher

Figure 2 L’vov’s original “graphite furnace atomizer. The
sample was deposited on the ”plug” (3) which was inserted
into the preheated graphite tube (1). An arc (5) was then struck
with an auxiliary electrode (4) to rapidly heat the plug and
release the sample into the tube and optical path. A tantalum
liner (2) was used in this original furnace to minimize analyte
loss from vapor diffusion through the graphite (Modern furnaces
use pyrolytically coated graphite through which minimal vapor
diffusion occurs). (Reprinted from B.V. L’vov, ‘The Analytical
Use of Atomic Absorption Spectra’, Spectrochim. Acta, 17,
761–770, Copyright (1961), with permission from Elsevier
Science.)

residence time within the furnace in comparison to a
flame. This paper and the promising results spurred a
great deal of activity in “flameless” atomizers.

Much of the initial work employed graphite-based
devices that were resistively heated, although many
were in the form of rods rather than the original
tubular design of L’vov. This was probably a result
of the ease of in-house manufacturing of making low
resistance contacts to carry the currents needed to
heat the rods. Much activity persisted in the 1970s
in trying different atomizer designs that ranged from
rods, to braids to tubular designs. The tubular design
ultimately dominated because of its ability to provide
a higher temperature, semi-enclosed environment. The
elevated temperature minimized compound formation
and condensation while the semi-enclosed nature of the
tubular design enhanced the residence time of the analyte
within the optical path to improve sensitivity.

The atomizer material was not limited to graphite, and
a number of high melting metals (e.g. W, Ta, Pt, etc.)
were evaluated. The metals often provided the advantage
of higher resistance and lower mass, thereby permitting
lower powers and the use of higher voltages (with lower
currents) to bring about rapid heating. For analytes that
tended to form refractory carbides on graphite, these
metal atomizers permitted complete vaporization at lower
temperatures. However, there were also a large number
of metals that dissolved in the metal atomizer or formed
solid solutions that produced memory effects as they were
slowly and continuously distilled from the atomizer with
each subsequent firing. Graphite probably remained
the material of choice for a number of reasons, although
the most readily apparent were its advantage of being
available at high purity, having a very high (ca. 3400 K)
sublimation temperature, and oxidizing to form a surface
“oxide” (C–O_ads) that was readily removed as CO_(g)
and CO_(2(g)) from the surface with simple heating. The size
of the tubular atomizers ranged from very small devices
that heated very rapidly and could only accommodate a
few microliters of sample, to the “Woodriff furnace”(4,5)
which approached 25 cm in length and was preheated
before the sample was introduced.

Significant among the developments was Massmann’s(6)
early design of a directly heated tube into which the
sample was introduced. This design precluded the striking
of an auxiliary arc as was required with the L’vov design.
Most modern furnaces are smaller versions of this design
with tube lengths typically ca. 2.5–3 cm with a 4–7 mm
inner diameter (Figure 3). As shown in Figure 3, the
furnace is heated from the ends (i.e. “end-heated”) by
direct passage of current through the furnace.

With the tube furnace, it became readily apparent that
analyte elements were often “stuck” near the ends of the
tube since the tube did not heat uniformly. Greater
heat loss was experienced where the ends of the furnace
contacted the water-cooled endcones and could result in
a temperature gradient as large as 1000 K between tube
center and end.(7) The heating of the furnace was more
uniform during a rapid deposition of energy into it (e.g.
during a rapid thermal ramp) and the ends tended to
cool as heating rates decreased or once a steady state
temperature in the tube center was achieved. This often
resulted in material vaporizing from the initial deposition
site and recondensing on the now cooler ends of the
furnace. As a result, the next heating of the atomizer
produced a secondary release of these condensed metals,
giving rise to memory effects. This was not uncommon,
especially for the more refractory analyte elements. To
minimize this problem, it was common to use higher

Figure 2 L’vov’s original “graphite furnace atomizer. The
sample was deposited on the ”plug” (3) which was inserted
into the preheated graphite tube (1). An arc (5) was then struck
with an auxiliary electrode (4) to rapidly heat the plug and
release the sample into the tube and optical path. A tantalum
liner (2) was used in this original furnace to minimize analyte
loss from vapor diffusion through the graphite (Modern furnaces
use pyrolytically coated graphite through which minimal vapor
diffusion occurs). (Reprinted from B.V. L’vov, ‘The Analytical
Use of Atomic Absorption Spectra’, Spectrochim. Acta, 17,
761–770, Copyright (1961), with permission from Elsevier
Science.)

Figure 3 This is a typical, modern end-heated graphite furnace
and workhead. The graphite furnace atomizer is in the center

atomization temperatures and “clean cycles” (i.e. high-
temperature heating of the furnace after the analytical
measurement was complete). Another alternative was
a redesign of the tube so that the electrical contacts
did not also serve as a heat sink that produced this
longitudinal temperature gradient. Isothermal cuvettes
(or “transversely heated graphite atomizers”) were
first introduced by Frech et al. to minimize thermal
gradients along the tube. Because of the more isothermal
environment and encouraging preliminary results, this
concept has made its way into the commercial market
and is another option to the end-heated furnace concept.

Another major breakthrough in use of furnaces was
initially suggested by L’vov et al. and involves the
use of a platform inserted into the furnace (Figure 4).
Since the formation of free atoms is favored at elevated
temperatures, it becomes problematic if a volatile analyte
(or analyte-containing compound) vaporizes at a low
temperature, which permits molecular species to form
(or remain). A small graphite flat in the furnace onto
which the sample is placed has minimal thermal contact
with the heated tube walls. As a result of poor conductive
heating of the platform by the wall, the temperature of the
platform lags that of the furnace walls. Depending on the
heating rate of the tube wall and the heat transfer rate
between wall and platform, this lag can be as large as
several hundred degrees. As a consequence, vaporization
of the sample from the platform into the furnace takes
place when the gas phase is at a higher temperature. This is
illustrated in Figure 4. Generally, the higher temperature
will sponsor molecular dissociation (atomization) and
both improve atomization efficiency as well as minimize
many interference effects. Because most platforms never
reach the wall temperature, the simple design depicted
in the figure is often not useable for the more refractory
elements such as V, Mo or even Ni and Cr. Alternative
designs of the platform where better thermal contact with
the wall exists are starting to appear on the market and
even determination of refractory metals with this new
design is feasible.

In the early days of flameless AA, carbon rod atomizers,
etc. the technique was plagued by extreme interference
effects. Some of the modifications noted above (i.e.
tube-type construction, isothermal heating and platform
use) ameliorated many of these problems. In spite of
these unique challenges, it was readily recognized that
vapor formation using an ETA was not limited by
factors that often plagued other spectroscopic techniques
where nebulizers were used for sample introduction.
For example, samples that were viscous, contained high
concentrations of total dissolved solids, or contained
suspended solids were often unusable with conventional
nebulization but could be dealt with using ETA. As a
result, expectations of high accuracy and precision were
appearing for samples containing extremely complex
matrices. These complex matrices placed heavy burdens
on the ability of the ETA to “synthesize” atoms within
the furnace consistently and with nearly 100% efficiency.

The use of chemicals added to the sample as “matrix
modifiers” became common place as a means of minimizing
matrix effects by permitting, for example, the removal
of the offensive matrix during a thermal pretreatment
step prior to the high temperature atomization heating
cycle. Ediger was often recognized as one of the first
to introduce such a concept with the suggestion that Ni
could be added to a sample that was being analyzed
for Se. His suggestion was that the Ni bound the Se
and “stabilized” it on the graphite surface to a higher
temperature while offending matrix concomitants could
be vaporized during the ash or thermal pretreatment
cycle. The delayed vaporization of the selenium until
the ETA was at a higher temperature also improved the
atomization efficiency. The search for and employment
of matrix modifiers continues to dominate the literature

---

**Figure 4** (a) Schematic diagram of a platform located inside a graphite furnace atomizer. The sample is initially deposited on the platform. (b) Representation of the temperature of the furnace wall and platform temperature during the pulse heating of the atomizer, that is “atomization cycle”. (Reproduced by permission from K.W. Jackson (ed.), Electrothermal Atomization for Analytical Atomic Spectrometry, Wiley, New York, 13, 1999.) The horizontal dashed line at 1000°C represents the appearance temperature. It should be noted that vaporization from the platform presents the analyte to the gas phase when the wall temperature is several hundred degrees hotter, thus promoting free atom formation.
as an important means of achieving reproducible and accurate analytical results in ETAAS. Many of the features alluded to above will be discussed in more detail in subsequent sections.

It is important to stress at this point that ETAAS is a powerful analytical technique that is widely used for ultratrace and microtrace analysis. It has the advantages of a high degree of elemental selectivity, and once a method is developed, analysis is relatively simple. Modern instrumentation has empowered the user with a high degree of automation, which further simplifies the use of ETAAS for a large number of samples. Inherent to AA, however, is its traditional single elemental analytical capabilities, that is, one element at a time can be determined. However, recent work in the area of using multiple sources and continuum sources may arm the approach with simultaneous multielement capabilities in future instruments.

The first sections discuss the theory behind the technique in an attempt to explain what is taking place within the atomizer at the molecular level. In this chapter there is also a brief discussion of “interferences” that can occur and why they are occurring, again to provide a complete picture of what is taking place fundamentally. However, the practical analytical utility of the approach should not be covered up by these discussions since, it will be shown, most of these potential problems can be circumvented with proper choice of instrument operating conditions and, in many cases, correct selection of matrix modifiers.

3 THEORY

3.1 Absorption Fundamentals

The basics of AA are also covered in Atomic Spectroscopy: Introduction. In brief, the absorption of radiation by the analyte within the furnace volume for the purpose of conducting analysis assumes the existence of free, gas-phase atoms. Analyte atoms present as molecular species (e.g. PbO, MnCl, etc.) or as ions (e.g. Na⁺) will not absorb at wavelengths used to detect the neutral atomic species. The preferred analytical lines for conducting AA in the ETA are identical to those used with flame atomic absorption (FAA) and are generally absorption transitions which originate in the unexcited atomic ground state and terminate in a higher lying electronic state, that is, resonance lines. For many atoms, there exists more than a single excited state that can be populated by an absorptive transition from the ground state. In these instances, the strength of the absorption is determined by the oscillator strength (or Einstein B coefficient for stimulated absorption). A larger value implies a higher probability of photon absorption and, hence, greater sensitivity. In some instances, the wavelength of the source wavelength may be noisier at this more strongly absorbing line and, as a consequence, the weaker line is used since it may provide an improved signal-to-noise ratio. For example, the 217-nm line for Pb is ca. 2.4 times more sensitive than the 283-nm resonance line, but the shorter wavelength is often noisier and more prone to interferences by scatter and molecular absorption. Hence, it is not uncommon to see the 283-nm line used in preference.

Lines which originate above the ground state generally show weaker signals since the strength of the absorption is directly dependent on the population of the low lying state. The magnitude of the absorption is governed by both the number of atoms within the optical path and the population of the absorbing state for those atoms. Generally 99% of the atoms will exist in the lowest excited electronic state (i.e. ground state) even at temperatures of 3000 K. Any of the higher lying states will be less populated and vary with temperature as dictated by the Boltzmann distribution. Hence, if absorbance measurements are being taken as the temperature within the furnace is changing, the atom density is not strictly proportional to the absorbance since the population of the originating state is changing.

It is possible that the absorbance measurement can be too large, that is it lies outside the dynamic range. When a given analyte concentration produces too large an absorbance signal, the sample can be diluted or an alternate absorbing line can be used. An alternate line that originates in the ground state but terminates in an upper state with a smaller oscillator strength is preferred since it will show minimal temperature dependence in comparison to an absorption that originates in a state above the ground state.

In general, the absorbance signal is proportional to the gaseous analyte mass within the furnace volume at any given instant in time. If the rate of analyte release into the gas phase is constant from standard-to-sample and from sample-to-sample, then the height of the absorbance signal (“peak absorbance”) could be used to construct a calibration curve. However, the peak shapes may change because of changes in vaporization rates caused by altered ETA heating rates, changes in vaporization mechanisms, etc. Therefore, the peak area is generally used in constructing the calibration curve and results in improved analytical accuracy. The peak area is calculated by integrating the absorbance signal over the lifetime of the peak and is expressed as peak area and has units of “per second” (since absorbance is dimensionless).

As with all atomic absorbance techniques, the linearity of the calibration curve is limited and covers only two to three orders of magnitude in concentration. The cause of the nonlinearity and apparent violation of Beer’s
law, can be a consequence of stray light, the finite width of the source line relative to the absorbing line or other more subtle spectral line shape alterations and spatial distributions of source radiation and analyte vapor. Lasers (e.g. diode lasers) can be more intense with less noise than conventional HCLs or electrodeless discharge lamps (EDLs). As a result, the lower concentration end of calibration curves may be extended, which results in improved detection limits and an enhancement in the dynamic range of ETAAS.

Like any AA technique, the likelihood of atomic spectral line interferences is low. This is a result of the narrow line widths of both the source and the absorber. Additionally, unlike emission spectroscopy, the number of atomic spectral lines that are capable of producing a significant absorbance signal is quite small. This is primarily a result of the need for a significant population of the originating state.

For any given radiation source (e.g. HCL), ETA is considered 100 to 1000 times more sensitive than FAA when comparing characteristic masses, that is the mass deposited in the furnace that is needed to produce a peak area of 0.0044 s. While some gain in sensitivity is garnered by the narrower absorbing line profile for atoms present in the furnace, most of the improvement results from the longer residence times of the atoms within the radiation beam with ETAAS. In a typical flame with a linear flame velocity of ca. 100 cm s⁻¹, the analyte atoms reside in the optical path for less than 10 ms. Atom residence times within the furnace are several tenths of a second to several seconds!

### 3.2 Production of the Atomic Absorption Signal

The typical sequence of events in the practical analysis of a sample involves the introduction of a sample (typically 10–25 µL of a solution) into the furnace through the dosing hole. A gentle dry cycle is initiated by heating the furnace to ca. 80–150 °C for 30–40 s to desolvate the sample. The proper choice of time and temperature is generally selected by viewing the sample using an inspection mirror (e.g. a small “dentist’s mirror”) through the furnace while drying to ensure that the droplet disappears completely and slowly, that is, no “splattering” from heating too rapidly. One or more thermal pretreatment cycles (sometimes referred to as an “ash”, “char”, or “pyrolysis”) are used to decompose some of the matrix and possibly to even remove the matrix if it is more volatile than the analyte. The temperature and times for this step vary considerably depending on the analyte, sample and matrix. For example, a simple sample containing a volatile element such as Cd, Zn or Pb may be heated to no more than 300–400 °C while a more refractory element such as Ni might be heated to 1200 °C or higher without fear of analyte loss. Finally, the atomization cycle is initiated where the furnace is rapidly heated (e.g. 1000–2000 °C s⁻¹) to a final temperature that is sufficient to remove all of the analyte from the furnace (e.g. 2000–2700 °C). It is during this cycle that the absorbance is recorded. Following the ramp, the furnace is often held for a few seconds at this elevated temperature. A clean cycle (2800–2900 °C) is sometimes initiated before cooling down to ensure complete vaporization and removal of any residuals from the sample.

In the following sections are discussions of the processes occurring during these heating cycles that ultimately lead to the generation of the transient absorbance signal from which quantitative analysis will be conducted. The discussion will begin with a look at the last cycle first (namely, the atomization cycle) and discuss the key steps leading to the production of gaseous atoms within the furnace ETA.

### 3.3 Basic Vaporization (Desorption) Process

The basic analytical signal is shown in Figure 5. As one might expect it is transient in character because the vapor generated by vaporization is not “trapped” in the furnace but is lost through the dosing hole and the ends of the furnace. There are some characteristics of the peak that are often alluded to and these are labeled in the diagram. The appearance time and temperature of the signal are $t_{app}$ and $T_{app}$ respectively. This is typically the time or temperature when the signal level has reached a magnitude that is three times the baseline noise level. The values are not thermodynamic in their origin, but do give an indication of when a signal will first appear and provide guidance regarding the atomization temperature that should be used. The time designations of $t_1$ and $t_2$.
provide some indication of the shape of the signal and have their origins in the original papers of L’vov who made the first attempts to explain the atom production process. \( t_1 \) is the “atomization time” and is measured from \( t_{app} \) to the peak time. \( t_2 \) is the time required for the peak absorbance to decay to 1/e of its value. In the initial treatment, L’vov suggested that minimizing \( t_1 \) and maximizing \( t_2 \) would place the maximum number of analyte atoms in the furnace volume and in the analytical volume. He proposed that rapid heating combined with a longer furnace would favor the total containment of the sample vapor in the furnace during the measurement period. Since this earliest work, we find now that the processes are somewhat more complex in many instances.

The mathematics describing the production of the analytical signal is a convolution of a time-dependent supply function, \( S(t) \), and a removal (or dissipation) function, \( R(t) \), as shown in Equation (1):

\[
N(t) = \int_0^\infty S(t) - R(t) \, dt
\]

where \( N(t) \) is the number of atoms in the analytical volume, that is, the furnace. \( R(t) \) must incorporate loss by: diffusion out of the ends of the furnace and the dosing hole; reactions in the gas phase that form analyte-containing molecules; readsorption, condensation, or sticking of the analyte to the furnace wall; nucleation in the gas phase to form condensed phase particles; and any other process which depletes the free atom density within the volume where the absorption measurement is made. \( S(t) \) includes the time-dependent production of gaseous analyte atoms by: vaporization (or desorption) from the surface; dissociation of analyte-containing molecules in the gas phase or on the surface (followed by metal vaporization); and any other source responsible for adding more atomic analyte to the gas phase.

3.3.1 Generation

Since the furnace is generally being heated while the transient absorption signal is produced, generation and loss functions must also account for the time-dependent temperature change, that is, nonisothermality of the furnace in time. Additionally, the furnace and the gas phase within the furnace may not be spatially isothermal, which must also be considered for an exact description of the shape of the signal. Thus, it is easy to see that even if the exact processes that contributed to \( N(t) \) were known, the solution to Equation (1) could be quite complex. Using overly simplified assumptions, however, does produce an \( N(t) \) versus \( t \) plot that is a reasonable approximation to what is observed. For example, one can assume that the number of gaseous atoms is proportional to the partial pressure of the analyte and assume that this pressure is dictated by equilibrium vapor pressures of the heated metal solid or liquid. Additionally, one can consider loss as a simple diffusive transport of material from the center of the furnace out the ends and ignore the dosing hole and any other loss pathway.

Since the number of analyte atoms on the surface is quite small, in many instances the analyte may not take on “bulk” thermodynamic characteristics. For example, if 20 pg of copper were evenly dispersed over a 2-mm-diameter area where the sample was initially dried, only about 5% of the surface would be covered. Thus, the energy required to produce copper vapor may not depend on the heat of vaporization \( (\Delta H_v) \) of Cu(1) but instead the energy needed to desorb adsorbed copper from graphite. In some instances where the interatomic forces are strong, it is possible that the metals on the surface diffuse and form small droplets of the “pure metal” in which case \( \Delta H_v \) is applicable to describe vapor production.

The mechanism of vapor production in an ETA has been an intense area of research interest for a number of years and is still not totally understood. One of the more interesting diagnostics that is often used attempts to extract the energy associated with the vaporization process and, by inference, to deduce the pathway by comparing the experimental value to literature values. The commonly cited approach was proposed by Sturgeon et al.\(^{18}\) and the resultant graph is often referred to as an “Arrhenius plot”, because its derivation is similar to that used in deducing reaction kinetics. In brief, it may be given by Equation (2):

\[
\ln(A) = \frac{-E_a}{kT} + C
\]

where \( A \) is the absorbance signal, \( E_a \) is the activation energy of release (often taken as \( \Delta H \)), \( k \) is the Boltzmann’s constant and \( T \) is the furnace temperature in Kelvin at the time the absorbance measurement is made. \( C \) is often assumed to be a constant and incorporates a number of terms including spectroscopic constants that relate an absorbance measurement to atom density (or pressure) as well as thermodynamic (or kinetic) values that are assumed to be temperature independent. In particular entropy change (or the pre-exponential factor when viewing the process as a kinetic process) is involved in this term.

Since the derivation of Equation (2) assumes that the analyte surface coverage (or condensed state activity) is not changing, the equation is most applicable (and most linear) at the very beginning of the absorbance signal. Smets\(^{19}\) added a modification to this basic equation that attempted to account for changing surface coverage and extends the linear portion of this plot later in time. The temperature is usually measured using optical pyrometry.
by viewing the inside of the furnace wall through the
dosing hole. This approach permits coverage starting at
c.a. 1100 K. Once a value for \(E_a\) (or \(\Delta H\)) is obtained,
interpretation to extract the vaporization step can often be
tenuous.

It is also possible that gaseous atoms originate directly
from molecular species. This includes thermal decompo-
sition of metal-containing compounds in the gas phase or
on the surface. In some instances, the surface reaction can
be thought of as a reduction or “thermoreduction” pro-
cess in which reactive carbon of the furnace participates
in the free atom formation as the temperature increases,
for example, reaction of a metal oxide with C to form free
gaseous metal atoms and CO or CO\(_2\).

3.3.2 Dissipation

Analyte loss from the analytical volume of the ETA can
take a number of forms, but in all cases the loss must be
irreversible. For example, metal gas colliding with the wall
of the ETA and sticking but revaporizing at a later time
during the measurement cycle would not be considered
“irreversible loss”. The simplest loss or dissipation is
diffusion of analyte from the ends of the furnace or out
of the dosing hole.

A simple equation, Equation (3), that considers the
continuous diffusive loss from the furnace ends was
proposed by L’vov

\[
\tau_2 = \frac{L^2}{8D}
\]

where \(\tau_2\) is the time required for the absorbance signal to
decrease to 1/e of its peak value, \(L\) is the furnace length
and \(D\) is the temperature-dependent diffusion coefficient.
This provides a reasonable approximation to the loss
rate by diffusion, but does not include loss from the
dosing hole. It also ignores the finite time at the onset
of vaporization for material to diffuse from the center to
the ends of the furnace to set-up a pseudo-steady-state
concentration. It also does not take into account the more
subtle loss mechanisms of recombination of the analyte
metal to form nonabsorbing molecular species.

3.3.3 Putting it Together

Use of the more complex geometry of the furnace
and the presence of a small, finite amount of sample
makes the solution to Equation (1) more complicated.
One approach to modeling the more realistic system
has employed the Monte Carlo technique.\(^{(20)}\) This is a
stochastic approach that permits complex geometries and
boundary conditions to be used in the construction of
a model. Figure 6 shows the results using Monte Carlo
simulation techniques to illustrate the time-dependent

Figure 6 Monte Carlo simulation showing the time-dependent
location of analyte atoms during a thermal heating cycle: (a) in
the furnace gas phase; (b) on the furnace wall; (c) lost out of the
dosing hole; and (d) lost out of the ends of the furnace. Data are
for a small (3 mm diameter \(\times 1\) cm long) furnace. (Reproduced
from Güell and Holcombe\(^{(20)}\) by permission of the American
Chemical Society.)

location and loss of analyte during a furnace heating cycle.
This simulation is for the production of copper vapor. As
can be seen, the leading edge of the gas phase signal rises
exponentially as the temperature ramp increases linearly.
As the amount of copper on the furnace wall decreases,
the generation rate falls off. The peak of the absorbance
signal represents the point where generation and loss rates
are equal, that is, \(S(t) = R(t)\). It should be noted that a
significant (ca. 20% in this case) amount of the analyte
is lost from the dosing hole and that analyte loss occurs
from the dosing hole before it is lost from the furnace
ends. The decrease in the atoms found on the tube wall
also does not conform to a simple exponential evolution
as might be surmised from a linear temperature ramp and
the assumption of “bulk amounts” of metal on the surface
(i.e. activity of metal is unity). In the case of copper, this is
a result of the release rate being dependent on the amount
of copper (i.e. surface coverage) on the graphite, which
changes with time (i.e. its activity decreases as material
is vaporized). As the surface coverage drops, the rate of
evolution decreases below that expected when surface
coverage is not taken into account.

3.4 Pretatomization Reactions

Many reactions occur on the surface prior to atom
production. These can be as simple as prevolatilization
of metal compounds and migration of material below
the surface. Some processes only impact the appearance
temperature and the shape of the analytical signal while
others can affect the number of free atoms produced.
The latter, of course, directly impacts analytical accuracy.
while the former may have little impact on accuracy when using the area under the absorbance signal. Most of these problems can be circumvented through the proper selection of temperature programming, a platform and chemical modifier.

Analyte prevolatilization involves the low temperature release of analyte-containing molecules at a temperature that is lower than that needed to thermally decompose these compounds. As a result, the absorbance signal is depressed. This is not uncommon for metal halides which are often relatively volatile but form stable metal halides in the gas phase. Some elements (e.g. selenium) also have volatile oxides that can also be lost from the furnace.

3.4.1 Decomposition

The form of the analyte salt residue that exists on the graphite surface after desolvation (“dry cycle”) can often be predicted by the dominant matrix anions and relative solubilities of the possible salts that could form. For example, the metal nitrate salt is likely in a nitric acid matrix, metal halides in a HCl matrix, etc. Depending on the solution pH, metal hydroxides are not unexpected. During the dry or char cycle, many of these salts decompose to the metal or metal oxides as shown in Equations (4) and (5):

\[
\text{M(NO}_3\text{)}_{2(s)} \rightarrow \text{MO}_\text{(s)} + 2\text{NO}_2 + \frac{1}{2}\text{O}_2 \quad (4)
\]

\[
\text{M(OH)}_{2(s)} \rightarrow \text{MO}_\text{(s)} + \text{H}_2\text{O} \quad (5)
\]

Easily reducible metals (e.g. Au, Ag, Cu, etc.) are likely present on the surface in the elemental form before atomization. There is little doubt that the graphite also serves as a reducing agent to assist this process for a number of metals as the furnace is heated.

Graphite also serves as a potentially problematic reactant as well as a reductant for elemental formation. Many metals bind very strongly to carbon to form stable surface species or even stoichiometric metal carbide compounds. These species are often very refractory and can be difficult to vaporize completely unless very high atomization temperatures are employed. Examples of these metals include W, Mo, Ta and Si. These stable carbides often precluded the use of platform technology (see section 4.4) since the platform may be incapable of reaching the wall temperature even with sustained heating times. Several workers have successfully used metal liners (e.g. Ta, W, etc.) placed inside the graphite furnace to circumvent this problem. However, metal liners cannot be permanently used because they limit the final atomization temperature to values substantially lower than that for graphite and can react with some analyte metals to form relatively stable solid solutions (e.g. alloys).

While the pyrolytic coating used on most commercial furnaces greatly reduces permeation of the sample liquid and gaseous vapor through the furnace walls, it is not single crystalline in character and has a considerable number of surface imperfections, dislocations and “cracks” in the surface. These features permit samples to migrate below the surface, perhaps as early as during the drying cycle and often as far as several micrometers. Majidi et al. have also shown that all metals do not behave the same. In many instances it is thought that the analyte forms intercalation compounds that are located in the interlamellar space between the graphitic sheets.

When metals that form intercalation compounds are present in large amounts such as quantities that might be present in a matrix or used in a chemical modifier, extensive damage to the furnace can occur. This is a result of these compounds causing an expansion in the interplanar spacing of the graphite which ultimately causes delamination and exfoliation of the material. The extreme result can include bending/warping of platforms and destruction of the furnace.

It should be noted in closing that it is not uncommon for materials to migrate on surfaces. Depending on the forces of attraction present, it is possible that adsorbed atoms, analyte-containing molecules and even small particles can move on the surface by surface diffusion. This diffusion can bring about the formation of small microdroplets of metals even if the metals were initially quite dispersed on the surface. Similarly, metals present as small droplets or islands initially may disperse on the surface as the temperature increases and entropy provides a driving force.

In some instances the appearance of migration occurs as material vaporizes (or desorbs) and is readsorbed at some distance away from the original site. This process occurs quite readily and can precede the appearance of the absorbance signal by several hundred degrees. The net result is a picture of the release of atoms into the gas phase that is not as simple as “vaporize, enter the gas phase and diffuse from the ETA”. With a mean free path of fractions of millimeters, there is ample opportunity for multiple collisions with the surface and readsorption at a measurable distance from the original sample deposition site.

3.4.2 Graphite–Oxygen Reaction

The importance of oxygen in forming metal oxides on the surface and in the gas phase has made studies of this “interferent” of special importance. Sources of oxygen include decomposition of oxycarbon salts, the sample solvent (water), impurities in the sheath gas and diffusion of atmospheric oxygen into the furnace through the dosing hole. Reduction of oxygen by the graphite furnace is thermodynamically favorable at all temperatures and should produce CO and CO₂, with
the CO : CO₂ ratio increasing at elevated temperatures if equilibrium is achieved. However, Sturgeon et al. were the first to suggest that this equilibrium was not likely achieved in the ETA until temperatures exceeded ca. 1500 K. This was later confirmed and presented in more detailed models. Sturgeon and Falk were the first to present experimental evidence of the partial pressures of oxygen in the furnace which was not based on inferences from the metal AA signal. Interestingly, the values agreed well with values chosen earlier by Cedergren et al. in their thermodynamic modeling of reactions within the furnace. In their studies they selected values that produced reasonable appearance temperatures for the metals under study.

As seen in the work of Gilmutdinov et al., the reactions of oxygen with the graphite present a complex time and spatial picture within the furnace. However, when combined with the authors’ spatial viewing of free atom densities within the ETV, it explains many of the unusual distributions that were observed. For example, the disappearance of many AA signals near the top of the furnace could be attributed to the infusion of air into the furnace through the dosing hole. Similarly, with the platform in place, some metals showed a particularly strong absorbance signal under the platform, which is consistent with a rarified oxygen atmosphere that would favor metal oxide dissociation.

In some analytical situations, oxygen is intentionally added to the sheath gas during the dry and thermal pretreatment stage. This is referred to as “oxygen ashing” and is most commonly done when there is a significant amount of a combustible material in the sample, e.g. a biological or low volatility organic matrix. Pyrolysis (i.e. heating to high temperatures in the absence of oxygen) of a biological matrix, for example, can leave copious amounts of carbon in the furnace even after the atomization cycle. Using oxygen admixed with the Ar, this matrix undergoes combustion and consumes the carbon as CO and CO₂. It is obviously critical that the oxygen be removed from the furnace if it is heated above ca. 800 °C since oxidation (and destruction!) of the graphite atomizer will occur.

3.4.3 Gas-phase Reactions

The presence of gas-phase reactions with the analyte will effectively reduce the free atom density and produce a signal depression. The depressed signal is of analytical importance if the source of the reacting species originates in the sample and is not present in the standard solutions. In many instances, standard addition is still capable of producing accurate results under these circumstances. The gas-phase reactions that are significant are, of course, metal-dependent, but as a general guide one must be cautious of halides and oxides, both of which can form stable gas-phase diatomic species with many metals. In most instances, dissociation of these diatomic species is favored at elevated temperatures. As a consequence platform technology is often recommended. Another alternative is to “thermally stabilize” the analyte with the use of a matrix modifier. This accomplishes two objectives. By delaying the analyte vaporization until a higher temperature, dissociation of analyte molecules on the surface or in the gas phase is enhanced. Additionally, if the analyte is not released until a higher temperature, then thermal pretreatment can be conducted at a higher temperature without fear of analyte loss. In many cases, this may permit the removal of the problematic matrix during this thermal stage prior to the atomization heating cycle.

The other option to reduce gas-phase interferences is to minimize the concentration of interferents in the sample through the use of matrix modifiers. As an example, the simple addition of HNO₃ to a chloride-containing sample results in a significant loss of the chloride as HCl during the dry cycle. Ammonium salts (e.g. NH₄H₂PO₄) are also used since the resulting NH₄Cl(s) is relatively volatile and provides a pathway to remove the chloride at relatively low thermal pretreatment temperatures.

4 INSTRUMENTATION

Modern ETAAS instrumentation includes a light source, background correction, the atomizer, the spectrometer and signal processing. Accessories would include autosampling systems and other attachments that maximize the performance and flexibility of ETAAS in the analytical laboratory. While other articles also discuss some aspects of the instrumentation (Atomic Spectroscopy: Introduction; Background Correction Methods in Atomic Absorption Spectroscopy; Flow Injection Analysis Techniques in Atomic Spectroscopy), this section will highlight aspects specific to ETAAS and provide some indication of current instrumentation as well as approaches that are on the horizon.

4.1 Light Sources

The traditional light source is the HCL which is a glow discharge source whose cathode is fabricated from the analyte metal(s) of interest and is contained within a sealed envelope surrounded by a few torr of an inert gas. The choice of fill gas is element-dependent. The glow (or Grimm) discharge is a low current (i.e. few milliamps) source that relies on sputtering and electron impact excitation for sampling and excitation, respectively. The source is not under local thermodynamic equilibrium and exhibits a very low kinetic temperature but a large electron temperature. As a consequence, a large number
of elemental lines are emitted but they have a very narrow half width, an ideal situation as a source for AA. Generally, a lamp provides the spectra for a single element. While multielement lamps are available, they usually provide reduced intensity for the elements within the lamp due to compromised excitation conditions and reduced sputtering efficiency because of fractional composition of the cathode material.

When low intensity from the HCL at the preferred wavelength presents a relatively high noise level, EDLs often become the source of choice. These devices are radiofrequency or microwave excited discharges which generally emit a more intense spectra. This is particularly useful for elements whose resonance lines are at shorter wavelengths such as As and Se.

More recently, tunable diode lasers have emerged as replacements for HCLs or EDLs. Because of their improved stability, narrow line width and reduced noise, diode laser sources have been used to record absorbance signals as low as $1 \times 10^{-6}$ absorbance units. As a consequence, larger dynamic ranges and significantly reduced detection limits appear possible. A commercial source of these lamps is currently available. Widespread use may be contingent on the development of diode lasers with fundamental wavelengths deeper into the blue region of the spectra so that simple frequency doubling is only needed to reach the short wavelengths (ca. 180–200 nm) where the resonance lines of many elements of interest lie.

A continuum source with a high resolution spectrometer has also been explored. Uniquely, it offers the possibility of simultaneous multielement analysis for ETAAS. However, the weak intensity of the source at low wavelengths has traditionally made this source less sensitive than traditional HCLs or EDLs, especially at shorter wavelengths. Consequently, its use has been primarily confined to the research laboratory. Recent work with diode array detectors suggests that comparable sensitivities are available even at the shorter wavelengths. This approach may become another viable alternative to traditional line sources.

### 4.2 Background Correction

This topic has been discussed in greater detail in the article *Background Correction Methods in Atomic Absorption Spectroscopy* in this publication. In general, background correction is much more critical in ETAAS than in FAA because of the higher local density of sample vaporized and the presence of cooler areas near the dosing hole and furnace ends where molecular species may form and/or condensation may take place. Additionally, ETAAS is often employed with samples that have a very high concentration of matrix components, with the extreme case of using the method for direct solids analysis.

#### 4.3 Atomizer

The atomizer has been discussed in general detail earlier in this chapter. In most cases the furnaces are fabricated from a high density “amorphous graphite”, often referred to as “electrographite”. This material is made from graphitized carbon at elevated temperatures but the crystals in the material are small and their orientation is random. While the density of the material is high (i.e. low porosity), it is not as great as pure graphite. This material is then coated with a 50 to 100-µm thick coating of “pyrolytic graphite” which is laid down by chemical vapor deposition techniques at elevated temperatures using a hydrocarbon gas as the source. (The temperatures and gas composition are usually proprietary information.) The coating makes the surface less permeable to diffusion by sample liquids and gaseous vapors. The coating is also more crystalline in nature with general orientation of the graphic planes parallel to the surface. The reactivity of the coating is generally significantly less than the electrographite substrate.

Most furnaces are of a Massmann-type design with power supplied to the furnace via contacts at the tube ends. As noted earlier, Frech et al. proposed an “isothermal cuvette” to minimize a temperature gradient that is known to persist from center-to-end in the more traditional furnace. A modification of the concept is commercially available as a “transversely heated graphite atomizer”. Figure 7 shows an example of these two furnace types. As noted in earlier sections, platforms or probes are a routine part of modern analysis by ETAAS. Depending on the design and intimacy of the contact between the platform and the tube wall, refractory metals may or may not be vaporized completely from the platform. In those designs where the platform is incapable of reaching the needed temperature, wall vaporization is used.

![Figure 7 Transversely heated graphite atomizer where the current to heat the furnace is not passed axially through the furnace from the ends. The design is intended to eliminate thermal gradients along the length of the tube to minimize cool spots in the tube where condensation refractory metals and/or molecular formation might occur. This particular design also has a platform machined into the furnace. (Reproduced by permission of PerkinElmer Instruments.)](image-url)
More recently, the addition to the ends of the furnaces of circular caps with holes in the centers has been suggested.\(^{(28)}\) These caps would reduce the rate of diffusive loss of analyte from the furnace and provide a more isothermal environment that may enhance sensitivity and reduce interferences. An even more dramatic change in furnace design has been proposed by Katskov et al.\(^{(29)}\) who use a “filter furnace”. In brief, the sample is deposited in a small chamber between the conventional filter wall and an insert within the tube that is fabricated from porous graphite. Upon heating, the sample diffuses through the hot porous graphite into the analytical volume. Results suggest fewer interferences while maintaining good sensitivity for the limited number of elements that they have considered.

### 4.4 Platforms and Probes

As was discussed at the start of this chapter and shown in Figure 4, the use of inserts (e.g. platforms or probes) is a common part of modern use of ETAAS. Platforms that have a more intimate thermal contact with the furnace wall will exhibit less of a thermal lag and may not prove as effective in dissociation of analyte-containing gas-phase molecules. However, this type of platform can be used for most analytes, including the more refractory elements.

### 4.5 Spectrometer and Optics

In general, the spectrometer is a medium or low resolution monochromator since it is only needed to isolate the resonance line of interest from other lines of the same element emitted from the line source, typically an HCL. Spectral bandpasses in the range of 0.1–5 nm are generally all that are required. The exception to this occurs when a continuum source is being considered in place of the HCL or other line sources. In this instance, a high throughput, high resolution spectrometer is preferred. To this end, an echelle spectrometer used in very high orders is the spectrometer of choice.

There are instruments which use several line sources which are alternately passed through the ETA and detection is made at several wavelengths. In this fashion the ETAAS system becomes capable of multielement analysis for a limited (four to eight) number of elements with a single firing of the atomizer.

Most systems are operated in a double beam mode where a chopper is used to alternately pass the source radiation through and around the ETA. In the case of the pulsed background correction, chopping is not needed since the same source provides on-line and off-line measurements (see Background Correction Methods in Atomic Absorption Spectroscopy). The path around the ETA is used primarily to correct for any drift in the source intensity. Additionally, the source may be modulated between the line source and the source used to register a background correction signal. For example, if an HCL is used with a D\(_2\) continuum source, the signals measured are typically: (i) the line source through the ETA measuring line and background absorbance; (ii) the continuum source through the ETA measuring background equivalent absorbance (and scatter); (iii) the line source around the ETA; and (iv) the continuum around the ETA to use as a measure of source stability and to register a zero absorbance level. Additionally, there is a fraction of the measurement cycle when no source radiation passes. During this period any emission from the furnace (blackbody, scatter, line or molecular) is registered and corrected for.

A photomultiplier tube is employed as the detector in most cases because of its low noise and high sensitivity. Solid-state detectors and array-type detectors may find greater use in the future but are minimally used in current AA systems.

### 4.6 Signal Processing

Because of the transient nature of the ETA signal, faster detection and processing is required than might be needed when the flame is used for atomization. Millisecond response times are often needed from the system to accurately reflect the transient signal. Collection rates of 20–120 Hz are typical for most modern instruments, yielding more than 100 measurement points to define a typical ETA signal of ca. 5 s duration. While faster modulation and collection could be used, the added noise from the more rapid collection generally does not compensate for the improved time resolution.

Most instruments provide the user with output of the time varying background-corrected atomic signal as well as the background signal. This can be useful in making an evaluation of whether the background level is of sufficient level that one should question the accuracy of the correction made by the instrument. Again, the article Background Correction Methods in Atomic Absorption Spectroscopy discusses the use and interpretation of the background signals.

Output is generally sent to a computer or “data station” where elaborate work up of the data takes place. Most instruments with a computer interface and high level software package permit the user to specify a number of analytical options, for example number and concentration of standards, number of replicates, options for standard additions and frequency of QA/QC checks. Additionally, most have capabilities of adding matrix modifiers from a separate reservoir to each standard and sample. Most software packages also provide complete reports on the analysis including information on the analytical precision
as well as the accuracy and precision of the calibration curve. Additionally, these same software packages furnish full statistical analysis of the results and permit use of such analytical tools as standard additions.

### 4.7 Autosamplers and Other Accessories

ETAAS can be highly automated. The key ingredient to such automation is the use of an autosampler for sample introduction. The autosampler (under computer control) not only frees up the operator, but it also provides one of the most precise means of micropipetting the sample into the furnace (i.e. <±3%). Many modern systems permit user input to the autosampler regarding the number of elements to be determined and number of replicates in each sample. The instrument then analyzes each sample and controls the spectrometer wavelength drive and source selector to cover all the elements of interest. In such an instrument, of course, the spectrometer must be set-up with a multilamp turret so that the lamps can be changed as one moves from sample to sample. Because of the improved precision and flexibility provided by the autosampler, most laboratories consider it as an essential part of a modern ETAAS system.

Other analytical schemes including flow injection analysis (see Flow Injection Analysis Techniques in Atomic Spectroscopy), hydride generation techniques (see Flame and Vapor Generation Atomic Absorption Spectrometry), slurries (see Slurry Sampling Graphite Furnace Atomic Absorption Spectrometry in Environmental Analyses) and solids directly are all available for use with ETAAS. In all the cases cited above, including direct solids analysis, high degrees of automation and sample handling are commercially available.

### 5 MATRIX MODIFIERS

A “matrix modifier” originally referred to a species that was added to the sample to improve the analytical accuracy and/or precision. It could be as simple as the addition of HNO₃ to assist in elimination of chloride as HCl during the dry cycle. The use of modifiers represents a cornerstone in practical utilization of ETAAS for chemical analysis. While there are literally hundreds of papers expounding on the virtues of various modifiers for particular analyte/matrix scenarios, most have been arrived at empirically and in most cases there is a minimal amount known about the actual physico-chemical interactions responsible for the observed improvements. Regardless of this unfortunate fact, many modifiers have sufficient documentation that one can feel comfortable that they will assist – if not ensure – the achievement of reliable analytical results. In all cases there are one or more fundamental functions that the modifier is intended to serve.

#### Matrix Removal

Some modifiers assist in the pre-volatilization of the matrix prior to the appearance temperature of the analyte in the gas phase. The removal may minimize coincidence of analyte and a matrix component in the vapor that would otherwise form a stable analyte-containing molecule and lead to a depressed signal. Examples include HNO₃ or NH₄⁺ for halide removal or use of oxygen ashing for combustion of biological compounds.

#### Analyte “Stabilization”.

By forming a more stable condensed phase species on the atomizer surface, higher thermal pretreatment temperatures may be used to remove unwanted matrix components. Examples include the addition of phosphate salts or the use of Pd (usually as the nitrate) to the sample and standards.

One of the more commonly used modifiers is Pd (usually as the nitrate salt). This appears to serve as a stabilizer for a number of metals. Obviously, it should not “stabilize” all species or it really serves no useful purpose except to delay vaporization of every sample component. The inclusion of Mg(NO₃)₂ in this solution has also been suggested to assist in the performance of the Pd modifier by acting as a “bulking agent”.

#### Surface Modification

A number of studies have modified the graphite surface in an attempt to enhance the atomization conditions of various analyte metals. Surface modification often involves the addition of large amounts of a metal salt (as a solution) to the furnace followed by thermal pretreatment to form, for example, a metal carbide coating on the surface. Metals have also been sputtered onto the graphite surface to accomplish the same purpose. This modified surface has been reported to improve atomization efficiencies and provide immunity to matrix problems. Metals that have been used include Ta and Ir. In contrast to the use of more conventional modifiers, these surface modification techniques need not be done prior to each firing of the atomizer.³⁰

There are certainly a large number of modifiers that have been used to satisfy certain analyte/matrix combinations. Some modifiers appear to be useful only for selected analyte/matrix combinations (e.g. Ni for semimetals) while others (e.g. Pd) have a broader application base. Tsalev and Slaveykova³¹ used multivariate techniques in an attempt to place some order in those that are reported to have worked. There is little doubt that many can be understood based on their chemical properties, but the mechanism for others remains elusive.
Most instruments come equipped with a methods manual or “cookbook”, which provides information on analyte-specific determinations. In many instances, procedures are often included for specific matrices; and in the newer instruments, this manual is on-line, that is, part of the data station or computer system that operates the system. Additionally, there are a large number of method development papers in the literature discussing specific analyte determinations in specific matrices that can be employed. These procedures can be used as an excellent starting point to initiate the analysis. This encyclopedia also presents some key analytical areas where ETAAS (also known as GFAAS) are employed (see Slurry Sampling Graphite Furnace Atomic Absorption Spectrometry in Environmental Analyses; Atomic Spectroscopy: Introduction; Background Correction Methods in Atomic Absorption Spectroscopy; Flame and Vapor Generation Atomic Absorption Spectrometry; and Flow Injection Analysis Techniques in Atomic Spectroscopy.)

As applied and fundamental research progressed, several instrumentation and methodological characteristics were generally acknowledged as adding significantly to analytical accuracy and precision. Slavin et al.\textsuperscript{(32)} attached the label of ‘stabilized temperature platform furnace’ conditions to these features. The embodiment of the general approach advocated the use of pyrocoated furnaces with a platform, rapid heating, fast responding digital electronics to accurately capture the transient signal, peak area (in place of peak height) for quantitation, Zeeman-effect background correction, and chemical modifiers. Some debate may persist regarding the universal applicability for all of these guidelines; but they are, in general, quite sound.

To follow is a generic approach to the set-up of a new method.

### 6.1 Setting Up Temperature Programs

#### 6.1.1 Sample Deposition and Dry Cycle

While depositing the sample, one can look through the end of the furnace toward the light source and see a shadow of the autosampler tubing that can be manually positioned in its deposition position. The tube should not make contact with the dosing hole sides, graphite wall or platform. When the droplet is deposited it should be “pulled” away from the tubing so that the tubing is not resting in the liquid after the sample is dispensed. An angled cut on the tubing often assists in improved sample deposition. The drying temperature should be set to a ramp of 5–10 s duration to ca. 80 °C (10–20 °C higher with platform) to begin and held at this temperature for 20–30 s. The criterion for adequate drying is to see the droplet gradually disappear over a period of 5–10 s with no noticeable boiling or bumping. Variations in temperature and time can be adjusted to achieve this. Drying is one of the more important steps since improper drying will lead to accuracy and precision problems as well as tube degradation. Bearing in mind the temperature setting and display on most instruments is not measured during the cycle, the error could be several tens of degrees at the low temperature settings.

#### 6.1.2 Thermal Pretreatment (“Char”)

It is almost always advisable to have a thermal pretreatment step if for no other reason than to eliminate any residual water and acids as well as some of the volatile matrix components in the sample. Additionally, this step is useful in decomposing many of the inorganic salts, for example, nitrates.

It is most critical that the analyte is not lost during this step. To evaluate this, “char curves” can be constructed. Simply set the dry to the predetermined setting and the atomization to a sufficiently high value to feel confident in achieving atomization, for example from standard procedure. Next, make a series of firings using your sample where the thermal pretreatment temperature is changed by ca. 100 °C but the time program is kept constant. A typical program might be a 5 s ramp to the temperature and hold for 20 s. The absorbance peak area is then recorded for each char temperature used. A curve similar to that shown in Figure 8(a) will result. The highest temperature is then selected where there is no attenuation of the peak area for the thermal pretreatment, ~900–1000 °C in this case.

![Figure 8](image-url)
6.1.3 Atomization Step

While a small gas flow through the atomizer is generally employed during the dry and thermal pretreatment steps, the atomization step is generally used in a “gas stop” mode (i.e. no flow through the furnace) to maximize residence time and to ensure maximum gas-phase temperatures.

The temperature setting for this step is critical. Too low an atomization temperature can produce a weak signal with memory effects while too high a temperature can cause excessive degradation of the furnace. Signs of too low a temperature include a badly tailing absorption peak. In most instances “step heating” (0 s ramp) is used for the atomization cycle. If a platform is used it is best to cool the atomizer to ca. 100 °C before initiating the atomization cycle. This provides the maximum time delay in the heating of the platform and should provide optimal results. After the ramp, the atomization temperature is usually held for ca. 5 s, sometimes longer if a platform is used and there is difficulty in removing the sample. If possible, it is always good to check the time-dependent temperature and absorbance signals to verify that a sufficient but not excessive hold time is being used.

Similar to the construction of a char curve, an atomization curve can be constructed. Using the previously determined dry and thermal pretreatment values and varying the atomization temperature, and noting the peak area, Figure 8(b) will result. An atomization temperature has to be selected where a minimum temperature yields the maximum area, ~1900–2000 °C in this case. If the area continues to rise even with the maximum temperature used, it is possible that the analyte is sticking to the graphite. If a platform is being used, you may have to use wall atomization (i.e. remove the platform). If wall atomization is used and the problem seems to persist at the highest temperature available, you can verify complete vaporization by checking for memory effects by running a blank after a sample (or standard solution). The presence of a signal in the blank suggests that the analyte is not being completely removed, assuming that the blank is analyte-free. Some modifier or change in sample preparation may be needed.

6.1.4 Clean Cycle

For some samples a short (5–20 s) clean cycle near the maximum temperature of the atomizer is advisable. This is essential if an analyte signal or background signal persists when a blank is fired immediately after a sample solution. Many analysts use this cycle as a routine part of their thermal program.

It is not uncommon to conduct a quick check of the instrument and its settings at the start of the analysis by computing the experimentally determined characteristic mass, $m_0$, with that provided by the manufacturer. The characteristic mass is the mass of analyte needed to register a peak area of 0.0044 s. Some manufacturers quote other figures of merit (e.g. sensitivity values), which can be used in a similar fashion to that of characteristic mass. Most instrument manuals or on-line documentation provide these values for a large number of elements, and the value is element and instrument-dependent. As an example, $m_0$ values range from a few tenths of a picogram to several tens of picograms, depending on the element and the instrument. The easiest way to determine $m_0$ is to analyze a standard that provides a peak area of ca. 0.05–0.2. By multiplying the analyte mass in this sample by 0.0044 and dividing by the peak area of the signal, the resulting value will be $m_0$. While a value checking sensitivity often lies within ±20% of the manufacturer’s tabulated value, a value that is no more than about two times the quoted value is reasonable assurance that there is no significant error in the methodology, instrument settings or lamp performance. Values that are much too high suggest that something is not quite right, for example lamp current is too high, temperature program is not correct, etc.

6.2 Sample Types

In most instances, ETAAS is used with 0–50 µL aliquots (20 µL being typical) of aqueous solutions, although analysis of slurries (see Slurry Sampling Graphite Furnace Atomic Absorption Spectrometry in Environmental Analyses) and solids are routinely conducted using this technique. Both of these approaches minimize sample handling and minimize or eliminate contamination because they minimize reagents needed to prepare a homogeneous solution sample. As alluded to earlier, gases (e.g. hydrides, as alluded to and discussed in Flame and Vapor Generation Atomic Absorption Spectrometry) and even aerosols have been analyzed by direct deposition into the furnace.

6.3 Calibration Curves

When a large number of samples are anticipated, the use of calibration curves is generally preferred over the method of standard additions. The method of standard additions can correct for enhancements or depressions that are multiplicative but cannot correct for additive problems such as background correction errors. It is not uncommon to encounter nonlinear calibration curves and most exhibit a dynamic working range of two to three orders of magnitude. With Zeeman background correction, roll-over may limit this range even more. Like FAA, the nonlinearity in the calibration curves is a result of a combination of factors including the finite width of the absorbing and emitting line, secondary lines within the
bandpass of the spectrometer and stray light reaching the detector. It has been suggested that contributions from nonuniform analyte distribution in the furnace combined with nonuniform spatial intensities from the line source may also contribute.\(^{(15)}\) Because of the nonlinearity, one must exercise caution in using standard additions since this analytical approach assumes linear extrapolation of the standard additions data to the intercept on the concentration axis. Most commercial software packages permit curve fitting to nonlinear curves, which optimizes the useful dynamic range.

Critical to all analyses by ETAAS is the use of high purity reagents (e.g. acids, water, etc.) because of the sensitivity inherent to the technique. As a standard analytical procedure, it is also advisable to employ standard reference materials (SRMs) as a quality control check during methods development and as a routine part of the analyses.

6.4 Absolute Analysis

The general approach of absorption spectrometry has possibilities of conducting analysis without the use of standards, that is, absolute analysis. As an example, ultraviolet/visible solution spectrophotometry with known solvent and solution environment can be used for analysis working with Beer’s law and knowledge of the proportionality between absorbance and concentration, that is, the molar absorptivity. It is acknowledged that there are certain caveats to do this successfully, but it can be done both in theory and practice. The success rests, in part, because absorption spectroscopy is a ratioing technique of the incident intensity with and without an absorber in the light path, that is, transmittance, and concentration is proportional to \(\log(1/T)\).

Variables in nebulizer efficiency, flame gas flows (as associated dispersion of analyte in the flame), optical path of source light through the flame, etc., eliminated the application of absolute analysis to FAA. However, L’vov\(^{(33)}\) recognized in his earliest work that this may be possible using ETAAS since a fixed volume was deposited in the furnace, atomization efficiency could be very nearly 100% and the full analyte could be retained in the analysis volume. (The latter fact was later modified to account for the continuous loss, and replaced by an assumption that the time spent by the analyte in the optical path could be constant and dependent only on furnace geometry if the analysis was conducted properly.) In essence, the approach suggested that one could calculate the peak area of the absorbance signal from fundamental spectroscopic constants combined with furnace geometry, thereby alleviating the need for preparing standard solutions and calibration curves. The potential of this concept was supported by experimental data from several laboratories.\(^{(34,35)}\) Agreement between calculated absorbance values and experimental values were generally within 20% of each other. This should be very encouraging especially when such accuracy may really be all that is needed in many samples where parts per billion levels are being determined. However, the conventional use of calibration curves with ETAAS often yields accuracy and precision values of <5%, which many regulatory agencies and “customers” of the analyst demand. To date, this potentially powerful feature of absolute analysis by ETAAS has not been routinely employed in any major segment of the analytical community.

7 CONCLUSION

Graphite furnace AA exists in the modern trace metal arsenal as a reliable and rugged analytical tool. With modern use of the technique, high precision (3–5% relative standard deviation) and accurate results can be obtained on a routine basis. With absolute LODs in the low picogram to subpicogram range (low parts per billion for relative LODs), it also becomes one of the most sensitive elemental analytical techniques. The ability to handle micro amounts of sample as well as complex samples (e.g. slurries, high dissolved salt matrices and even solids) has made ETAAS a very attractive option when limited sample amounts or complex matrices are encountered. Like all atomic spectroscopic techniques, the production of free atoms is essential to the analytical success of ETAAS. With modern furnace designs, matrix modifiers and a wide range of published procedures, the analyst has the key ingredients for obtaining reliable results.

Since its inception, a large number of fundamental studies have been conducted on the ETA and considerable knowledge gained on the processes preceding the formation of the free atoms. Many of the improvements in this technique have resulted from judicious use of this information. Similarly, this basic information is often of use in efficiently extracting solutions to analytical problems that are encountered with a new analyte or matrix.

1 Introduction

ICP-OES is one of the most powerful and popular analytical tools for the determination of trace elements in a myriad of sample types (Table 1). The technique is based upon the spontaneous emission of photons from atoms and ions that have been excited in an RF discharge. Liquid and gas samples may be injected directly into the instrument, while solid samples usually require extraction or acid digestion so that the analytes are present in a solution. The sample solution is converted to an aerosol and directed into the central channel of the plasma. At its core, the inductively coupled plasma (ICP) sustains a temperature of approximately 10 000 K, so the aerosol is quickly vaporized. Analyte elements are liberated as free atoms in the gaseous state. Further collisional excitation within the plasma imparts additional energy to the atoms, promoting them to excited states. Sufficient energy is often available to convert the atoms to ions and subsequently promote the ions to excited states. Both the atomic and ionic excited state species may then relax to the ground state via the emission of a photon. These photons have characteristic energies that are determined by the quantized energy level structure for the atoms or ions. Thus, the wavelength of the photons can be used to identify the elements from which they originated. The total number of photons is directly proportional to the concentration of the originating element in the sample.

The instrumentation associated with an ICP-OES system is relatively simple. A portion of the photons emitted by the ICP is collected with a lens or a concave...
mirror. This focusing optic forms an image of the ICP on the entrance aperture of a wavelength selection device such as a monochromator. The particular wavelength of light exiting the monochromator is converted to an electrical signal by a photodetector. The signal is amplified and processed by the detector electronics, then displayed, and stored by a personal computer.

The characteristics of the ICP as an analytical atomic emission source are so impressive that virtually all other emission sources (such as the flame, microwave-induced plasma (MIP), direct current plasma (DCP), laser-induced plasma (LIP), and electrical discharge) have been relegated to specific, narrowly defined application niches. Indeed, even much of the application field originally assigned to flame atomic absorption spectrometry (FAAS) and graphite furnace atomic absorption spectrometry (GFAAS) has been relinquished to the ICP. Compared to these other techniques, ICP-OES enjoys a higher atomization temperature, a more inert environment, and the natural ability to provide simultaneous determinations for up to 70 elements. This makes the ICP less susceptible to matrix interferences, and better able to correct for them when they occur. In cases where sample volume is not limited, ICP-OES provides detection limits as low as, or lower than, its best competitor, GFAAS, for all but a few elements. Even for these elements, the simplicity with which the ICP-OES instrument is operated often outweighs the loss in sensitivity.

2 THEORY

The ICP was developed for OES by Fassel et al. at Iowa State University in the United States and by Greenfield et al. at Albright & Wilson, Ltd. in the United Kingdom in the mid-1960s.\(^1\,9\,10\) The first commercially available ICP-OES instrument was introduced in 1974. The ICP is now not only the most popular source for OES but it is also an excellent ion source for mass spectrometry: inductively coupled plasma mass spectrometry (ICPMS).\(^11\) ICP-OES is a proven commercial success, and the future is still bright for ICP-based spectroscopic techniques. Detectability has been continuously and dramatically improved over the past 45 years. Detection limits, for example, have improved by a factor of 4–6 orders of magnitude for many elements. Nevertheless, research and commercial opportunities for further development of ICP-OES remain intriguing.\(^11\)

### 2.1 Inductively Coupled Plasma Operation

As shown in Figure 1, the so-called ICP torch is usually an assembly of three concentric fused-silica tubes. These are frequently referred to as the outer, intermediate, and inner gas tubes. The diameter of the outer tube ranges from 9 to 27 mm. A water-cooled, two- or three-turn copper coil, called the load coil, surrounds the end of the torch and is connected to an RF generator. The outer argon flow (10–15 \(L\,min^{-1}\)) sustains the high-temperature plasma, and positions the plasma relative to the outer walls and the induction coil, preventing the walls from melting and facilitating the observation of emission signals. The plasma under these conditions has an annular shape. The sample aerosol carried by the inner argon flow (0.5–1.5 \(L\,min^{-1}\)) enters the central channel of the plasma and helps to sustain the shape. The intermediate argon flow (0–1.5 \(L\,min^{-1}\)) is optional and may serve the functions of pushing the plasma slightly away from the end of the central sample tube, or diluting the inner gas flow in the presence of organic solvents.

The ICP is generated as follows. RF power, typically 700–1500 W, is applied to the load coil and an alternating current oscillates inside the coil at a rate corresponding to the frequency of the RF generator. For most ICP-OES instruments, the RF generator has a frequency of either 27 or 40 MHz. The oscillation of current at this high

frequency causes the same high-frequency oscillation of electric and magnetic fields to be set up inside the top of the torch. With argon gas flowing through the torch, a spark from a Tesla coil is used to produce “seed” electrons and ions in the argon gas inside the load coil region. These ions and electrons are then accelerated by the magnetic field, and collide with other argon atoms, causing further ionization in a chain-reaction manner. This process continues until a very intense, brilliant white, teardrop-shaped, high-temperature plasma is formed. Adding energy to the plasma via RF-induced collision is known as \textit{inductive coupling}, and thus the plasma is called an ICP. The ICP is sustained within the torch as long as sufficient RF energy is applied.\cite{1} In a cruder sense, the coupling of RF power to the plasma can be visualized as positively charged Ar ions in the plasma gas attempting to follow the negatively charged electrons flowing in the load coil as the flow changes direction 27 million times/s. The multitude of collisions produced in this environment gives rise to the energy transferred to the sample. No combustion reactions occur in the plasma.

Figure 1 shows the temperature gradient within the ICP with respect to distance from the load coil. It also gives the nomenclature for some of the different zones of the plasma as suggested by Koirtyohann et al.\cite{12} The induction region (IR) encircled by the load coil is “doughnut-shaped” as described above, and it is the region where the inductive energy transfer occurs. This is also the region of highest temperature and it is characterized by a bright continuum emission. From the IR outward toward the tail plume, the temperature decreases.

An aerosol, or very fine mist of liquid droplets, is generated from a liquid sample by the use of a nebulizer. The aerosol is carried into the center of the plasma by the argon gas flow through the IR. Upon entering the plasma, the droplets undergo three processes. The first step is desolvation, or the removal of the solvent from the droplets, resulting in microscopic solid particulates, or a dry aerosol. The second step is vaporization, or the decomposition of the particles into gaseous-state molecules. The third step is atomization, or the breaking of the gaseous molecules into atoms. Finally, excitation and ionization of the atoms occur, followed by the emission of radiation from these excited species. The analytical signal is normally observed through an end-on (axial) viewing position.

\section{2.2 Inductively Coupled Plasma Characteristics}

The main analytical advantages of the ICP over other excitation sources originate from its capability for efficient and reproducible vaporization, atomization, excitation, and ionization for a wide range of elements in various sample matrices. This is mainly due to the high temperature, 6000–8000 K, in the observation zones of the ICP. This temperature is much higher than the maximum temperature of flames or furnaces (3300 K). The high temperature of the ICP also makes it capable of exciting refractory elements and renders it less prone to matrix interferences. Other electrical-discharge-based
sources, such as alternating current and direct current arcs and sparks, and the MIP, also have high temperatures for excitation and ionization, but the ICP is typically less noisy and better able to handle liquid samples. In addition, the ICP is an electrodeless source, so there is no contamination from the impurities present in an electrode material. Furthermore, it is relatively easy to build an ICP assembly and it is inexpensive, compared to some other sources, such as a LIP. The following is a list of some of the most beneficial characteristics of the ICP source:

- high temperature (6000–8000 K);
- high electron density ($10^{14} – 10^{16}$ cm$^{-3}$);
- appreciable degree of ionization for many elements;
- simultaneous multielement capability (over 70 elements including P and S);
- low background emission, and relatively low chemical interference;
- high stability leading to excellent accuracy and precision;
- excellent detection limits for most elements (0.03–10 ng mL$^{-1}$);
- wide linear dynamic range (LDR) (4–6 orders of magnitude);
- applicable to the refractory elements;
- cost-effective analyses.

3 SAMPLE INTRODUCTION

An introduction system is used to transport a sample into the central channel of the ICP as a gas, vapor, aerosol of fine droplets, or solid particles. The general requirements for an ideal sample introduction system include amenity to samples in all phases (solid, liquid, or gas), tolerance to complex matrices, the ability to analyze very small amounts (<1 mL or <50 mg), excellent stability and reproducibility, high transport efficiency, simplicity, and low cost.\(^{(2)}\) A wide variety of sample introduction methods have been developed, such as nebulization, hydride generation (HG), electrothermal vaporization (ETV), laser ablation, and direct sample insertion (DSI).\(^{(1,13–17)}\) The analysis of liquid microsamples, at flow rates less than 0.1 mL min$^{-1}$, is also possible.\(^{(18,19)}\) The most popular sample introduction methods are described below.

3.1 Nebulizers

Nebulizers are the most commonly used devices for solution sample introduction in ICP-OES. Pneumatic nebulizers make use of high-speed gas flows to create an aerosol, while the USN breaks liquid samples into a fine aerosol by the ultrasonic oscillations of a piezoelectric crystal. The formation of aerosol by the USN is therefore independent of the gas flow rate.

Only very fine droplets (about 8 µm in diameter) in the aerosol are suitable for injection into the plasma. A spray chamber is placed between the nebulizer and the ICP torch to remove large droplets from the aerosol and to dampen pulses that may occur during nebulization. Thermally stabilized spray chambers are sometimes employed to decrease the amount of liquid introduced into the plasma, thus providing stability especially when organic solvents are involved. Pneumatic nebulization is very inefficient, however, because only a very small fraction (less than 5%) of the aspirated sample solution actually reaches the plasma. Most of the liquid is lost down the drain in the spray chamber. However, the pneumatic nebulizer retains its popularity owing to its convenience, reasonable stability, and ease of use. Efficiency may only be a concern when sample volumes are limited or measurements must be performed at or near the detection limit.

Three types of pneumatic nebulizers are commonly employed in ICP-OES: the concentric nebulizer, the cross-flow nebulizer, and the Babington nebulizer (Figure 2). The concentric nebulizer is fashioned from fused silica. The sample solution is pumped into the back end of the nebulizer by a peristaltic pump. Liquid uptake rates may be as high as 4 mL min$^{-1}$, but lower flows are more common. The sample solution is pumped into the back end of the nebulizer by a peristaltic pump. Liquid uptake rates may be as high as 4 mL min$^{-1}$, but lower flows are more common. The sample solution flows through the inner capillary of the nebulizer. This capillary is tapered so that flexible tubing from the pump is attached at the...
entrance (4-mm outer diameter) and the exit has a narrow orifice approaching 100 \(\mu\)m or less in inner diameter. Ar gas \((0.5–1.5 \text{ L min}^{-1})\) is supplied at a right angle into the outer tube. This tube is also tapered so that the exit internal diameter approaches the outer diameter for the sample capillary. As the Ar gas passes through this narrow orifice, its velocity is greatly increased, resulting in the shearing of the sample stream into tiny droplets. Concentric nebulizers have the advantages of excellent sensitivity and stability, but the small fragile fused-silica orifices are prone to clogging, especially when aspirating samples of high salt content. Concentric nebulizers also require a fairly large volume of sample, given the high uptake rate. The microconcentric nebulizer (MCN) is designed to solve this problem. The sample uptake rate for the MCN is less than 0.1 mL min\(^{-1}\). The compact MCN employs a smaller diameter capillary (polymide or Teflon) and poly(vinylidine difluoride) body to minimize the formation of large droplets and to facilitate the use of hydrofluoric acid.

A second type of pneumatic nebulizer, the cross-flow nebulizer, is designed to reduce the clogging problem. In contrast to concentric nebulizers, cross-flow nebulizers use a high-speed stream of argon perpendicular to the tip of the sample capillary. Again the sample solution is broken into an aerosol, as shown in Figure 2. The drawbacks of the cross-flow nebulizer include lower sensitivity and potential capillary misalignment.

The third type of pneumatic nebulizer used for ICP-OES is the Babington nebulizer that allows a film of the sample solution to flow over a smooth surface having a small orifice (Figure 2).\(^{20}\) High-speed argon gas emanating from the hole shears the sheet of liquid into small droplets. In some cases, the liquid may be guided over the argon orifice by positioning both the orifice and the sample introduction port at the base of a V-shaped groove (V-groove nebulizer). The essential feature of the Babington nebulizer is that the sample solution flows freely over a small aperture, rather than passing through a fine capillary, resulting in a high tolerance to dissolved solids. In fact, even slurries can be nebulized with a Babington nebulizer.\(^{21}\) This type of nebulizer is the least susceptible to clogging and it can nebulize very viscous liquids.

The Hildebrand grid nebulizer (HGN) (Figure 3) may be considered a specialized version of the Babington nebulizer with many orifices. Often the nebulizer has a screw-cap design. The outer member (cap) of the nebulizer holds two parallel platinum screens or grids. The grids are separated by approximately 2 mm. The inner body of the nebulizer (screw) has a single sample channel. Liquid is pumped through this channel at rates up to 1 mL min\(^{-1}\). The inner body also has a circular V-groove that allows the liquid to contact the entire perimeter of the inner platinum grid. In this fashion, the liquid completely wets both grids. A high-velocity stream of argon (1 L min\(^{-1}\)) blows through the center of the nebulizer. Often the velocity of the argon is increased by placing a sapphire crystal containing a small orifice (0.2 mm) in the center of the gas stream. The high-velocity argon forces the liquid through the tiny openings in the screens producing a fine aerosol. The HGN is characterized by clog-free operation, high efficiency, and excellent stability.

With the USN, sample solution is first introduced onto the surface of a piezoelectric transducer that is operated at a frequency between 0.2 and 10 MHz. The longitudinal wave, which is propagated in the direction perpendicular to the surface of the transducer toward the liquid–air interface, produces pressure that breaks the liquid into an aerosol.\(^{22}\) The efficiency of an USN is typically between 10 and 20%. This nebulizing efficiency is greater than that of a pneumatic nebulizer, and it is independent of argon flow rate. Therefore, a slower gas flow rate can be used to transport the aerosol to the plasma, thus prolonging the residence time of analyte in the plasma. This can result in improved sensitivity, and the limit of detection (LOD) may be lowered by a factor of 8–200, depending upon the element. However, the USN is more complicated, more expensive, and more susceptible to matrix effects, memory effects, and high solid loading. The USN is not compatible with hydrofluoric acid.

While the efficiency of each type of nebulizer depends upon the specific ICP-OES instrument employed (and its power, gas, and flow parameters), some comparisons are possible. Table 2 compares the relative magnitude of LODs observed for 11 elements using four different nebulizers. Since the USN provides the lowest LOD in each case, its value is set to 1, and the other LODs are higher by the factor listed in the table. Using these 11 elements as representative cases, on an average, LODs follow the trend USN < HG < concentric < V-groove.\(^ {(3,23)}\) Various other means of nebulization have been tested with limited degrees of success.\(^ {22}\)
Table 2 Relative ICP-OES LOD observed using different nebulizers (3,23)

*The relative LOD is the ratio of the LOD using a given nebulizer to the LOD for the USN.*

3.2 Hydride Generation

Hydride generation (HG) is a very effective sample introduction technique for some elements. These elements include arsenic, bismuth, germanium, lead, antimony, selenium, tin, and tellurium. In this method, the sample in diluted acid solution is mixed with a reducing agent, usually a solution of sodium borohydride in dilute sodium hydroxide. The reaction of sodium borohydride with the acid produces hydrogen. The hydrogen then reduces the analyte metal ions to hydrides, which are gaseous at ambient temperatures. The chemical reactions are shown in Equations (1) and (2).

\[
\text{NaBH}_4 + 3\text{H}_2\text{O} + \text{HCl} \rightarrow \text{H}_3\text{BO}_3 + \text{NaCl} + 8\text{H} \quad (1)
\]

\[
8\text{H} + \text{E}^{m+} \rightarrow \text{EH}_n + \text{H}_2 \quad \text{(excess)} \quad (2)
\]

where \( \text{E} \) is the hydride forming element of interest and \( m \) may or may not equal \( n \).

The advantages of the HG technique include:

- slow reactions, necessitating hydride trapping prior to introduction;
- critical control of experimental conditions such as pH and reagent concentrations;
- extra influential factors, such as the oxidation state of the analyte of interest.

LODs for the hydride generating elements are listed in Table 3, together with those observed for conventional nebulization techniques. The LODs of HG-ICP-OES in Table 3 are the best LODs cited in Nakahara’s review paper (13). Compared with conventional pneumatic nebulization techniques, LODs achieved by the HG technique are enhanced by a factor between 10 and 1000, depending upon the element.

3.3 Electrothermal Vaporization

Electrothermal vaporization (ETV) has also been used to solve problems associated with pneumatic nebulization. Graphite furnaces or other electrothermal devices, such as carbon rods, carbon cups, graphite boats, graphite tubes, tungsten wire, and other metal filaments, have been used in research laboratories to electrothermally vaporize a liquid or solid sample for introduction into the ICP. (14,15,24) Other vaporization methods, such as arc/spark vaporization and laser ablation/vaporization, have also been used as a means for sample introduction in ICP-OES. Even the ICP itself has been used to vaporize samples into a second ICP for analytical measurements. (25) In a typical experiment, a low current is applied to the ETV to remove the sample solvent. A small portion of the sample is then vaporized by the device through the application of a high current. An optional “ash” step may be used to remove some of the matrix prior to the analyte vaporization step. The resulting dense cloud of the analyte vapor is then efficiently swept into the center of the plasma by a flow of argon gas.

A commercial graphite furnace designed for atomic absorption spectrometry (AAS) is most frequently used...
in ETV-ICP-OES. The major advantage of ETV as a means of sample introduction is that the transportation efficiency is dramatically improved over a pneumatic nebulizer, from less than 5% to over 60%. Consequently, the LODs are improved by at least an order of magnitude. Some difficult-to-analyze samples, those with high total dissolved solids (TDS), for example, can be introduced by the ETV. However, since these devices are generally not of a continuous-flow nature, the ICP instrument has to be capable of recording transient signals. Also, the simultaneous multielement capability of the system could be limited owing to this transient nature of signals. Furthermore, when graphite material is used for the ETV, carbide formation could be a problem for some elements, resulting in lowered sensitivity and memory effects for refractory elements.

In an attempt to eliminate the problems associated with graphite, metal filaments have been employed for ETV-ICP-OES. For example, a tungsten coil from a commercial slide projector bulb can be used to vaporize liquid samples prior to their introduction into the ICP. A small volume, typically 20 µL, of sample solution is delivered to the tungsten coil and dried at low current. Then, a higher current is applied to atomize the sample from the coil. The vapor is then rapidly introduced into the plasma as a dense plug by a flow of argon/hydrogen gas. The LOD is typically improved by 100–1500 times compared with pneumatic nebulization. These LODs are comparable to those obtained by GFAAS, but with the capability of simultaneous multielement measurement, and at a low cost. A tungsten loop has also been used as an in-torch vaporization (ITV) means for sample introduction to the ICP, and the operation can possibly be automated. These approaches still share some of the other disadvantages associated with graphite furnace ETV, and commercial systems have not yet appeared.

3.4 Chromatographic Couplers

The combination of the separation power of chromatography and the detection power of atomic emission spectroscopy results in many advantages. One of the primary advantages of chromatography over conventional sample introduction is the ability to obtain speciation information. When used as a detector for chromatographic methods, the ICP offers good sensitivity, wide LDR, and multielement detection capability. The multielement capability of the ICP, in turn, enhances the performance of chromatographic methods. Both gas chromatography (GC) and high-performance liquid chromatography (HPLC) can be coupled with ICP-OES. Compared with HPLC, however, the GC-ICP coupling is less common because the analytical performance of ICP-OES is often not adequate for the typical non-metal-containing analytes separated by GC. Undoubtedly, GC-ICP-OES is still useful in the analyses of volatile organometallics, as demonstrated in the determination of methylmercury species. The successful combination of these two techniques is realized through the use of chromatographic couplers. Fortunately, most of the interface systems currently in use are relatively inexpensive and easy to construct, and they require few, if any, modifications to commercial ICP-OES instruments.

Direct connections between the end of the HPLC column and the nebulizer suffer from poor transport efficiency and low tolerance to many of the organic solvents commonly employed in mobile phases for HPLC, particularly when a pneumatic nebulizer is used. To improve the transport efficiency and to minimize the influence of organic solvents on the stability of the ICP, USNs, water-cooled thermospray chambers, and glass-frit nebulizers have been utilized for sample introduction in HPLC-ICP-OES. The solvent load on the plasma can also be decreased by aerosol thermostating, increasing the incident RF power, application of a condenser, or by use of a micro-HPLC column.

Other major sample introduction methods, such as thermospray, DSI, and laser ablation, have also been used for ICP-OES. Each of these has its advantages and disadvantages. For example, laser ablation can be used to vaporize any solid samples into the ICP, but generally it has poor reproducibility and high cost.

4 TORCH CONFIGURATION

The atomic emission from the plasma, as shown in Figure 1, is sampled for spectrometric measurements. Two configurations may be employed for observing emission from the ICP. One is referred to as a radial or side-on viewing of the plasma, and the other is known as an axial or end-on viewing of the plasma (Figure 1). A third viewing mode is the combination of these two basic modes, and is known as dual view. These are all commercially available, and each of them has advantages and disadvantages.

4.1 Radial View

The radial view is the classical operation mode for ICP-OES. With radial viewing, the plasma is operated in a vertical orientation, and the analytical zone is observed from the side of the plasma. This mimics the classical viewing orientation for atomic emission from a flame. Radial viewing constrains the observation volume to the distance through the diameter of the plasma. Since this pathlength is limited, sensitivity is also limited, but
so are the effects of potential spectral and background interferences.

4.2 Axial View

With the axial view, the plasma is rotated to a horizontal position and the emission signal is observed from the end of the plasma. The axial view provides better LODs than radial view. This may be attributed to the longer viewing path available down the axis of the plasma. Thus, a better sensitivity and a 5- to 10-fold improvement in the LOD can be achieved. The disadvantages of the axial view include the increased potential for spectral interference and matrix-induced interferences. Moreover, self-absorption effects can be quite severe because the observations are made through the much cooler tail plume of the plasma. These effects can be significantly reduced by use of a shear gas, or an appropriate optical interface, which displace the tail plume from the optical path, thus reducing the self-absorption (Figure 1). Spectral interferences may be either corrected or minimized by improving spectral resolution, using an alternate analytical line with less or no interference, or by applying an interelement correction (IEC) factor.

4.3 Dual View

In cases of very complicated sample matrices having a wide range of elemental concentrations, the axial view may be inappropriate. Several commercial instruments combine the axial view and radial view configurations into a single unit, known as dual view. This dual view system allows the user to optimize the appropriate configuration for the type of sample without the expense of two separate ICP-OES systems.

5 DETECTION OF EMISSION

5.1 Gratings

ICP-OES is characterized by remarkably rich spectra. For example, the 70 elements most commonly determined by the technique give rise to at least 70,000 total emission lines in the 200–600-nm wavelength range. A consequence of this high density of spectral information is the need for high resolving power. The low-resolution dispersive systems typically employed with atomic absorption spectrometers will not suffice. Spectral interferences occur in this case if only a small number of elements are present at moderate concentrations in the sample. Much higher resolution is desirable in ICP-OES, with spectral bandpass (Δλ) 0.01 nm or lower, if possible. Traditionally, this degree of resolution has been accomplished using plane grating monochromators with large focal lengths (f = 0.5 m or more).

Figure 4 depicts a plane-ruled grating. The normal to the grating surface (N) is shown as a dashed line. A light ray incident to the grating approaches at angle α measured with respect to N. The diffracted ray leaves the grating surface at angle β. Parallel rays striking the grating on different adjacent groove facets travel a different distance before reaching a common position beyond the grating. If the difference in distance traveled is a multiple of the wavelength of the light incident upon the grating surface, then the rays undergo constructive interference. Otherwise, destructive interference occurs. Relatively simple geometrical considerations result in the grating formula shown in Equation (3):

\[ d(\sin \alpha + \sin \beta) = m\lambda \]

This equation shows the relationship between α, β, the groove spacing (d), the wavelength of light (λ), and the order of diffraction (m). The order of diffraction may take any integer value including zero. At zero order, all wavelengths undergo constructive interference at the same diffraction angle. In the first order, one particular wavelength undergoes constructive interference at the angle β that corresponds to the specular reflection angle for rays incident at angle α. This wavelength is called the blaze wavelength for the grating, and it is determined by the angle at which the grooves are cut with respect to the surface of the grating. A grating is most efficient at its blaze wavelength. Typically, a grating may have an efficiency as high as 70% at its blaze wavelength, so the intensity measured at the blaze wavelength is 70% of the intensity that would be measured at the specular reflectance angle for a polished mirror of the same coating and material as the grating.
Normally, when a plane grating is employed, the angle of incidence is nearly 0, so $\sin \alpha$ approaches 0. In this case, the grating formula may be further reduced, as shown in Equation (4):

$$\sin \beta = \frac{m \lambda}{d}$$ (4)

The angular dispersion of the grating ($d\beta/d\lambda$) may be found, as shown in Equations (5) and (6), by taking the derivative of both sides of the above equation with respect to $\lambda$:

$$(\cos \beta) \frac{d\beta}{d\lambda} = \frac{m}{d}$$ (5)

$$\frac{d\beta}{d\lambda} = \frac{m}{d \cos \beta}$$ (6)

The angular dispersion therefore increases with larger order, smaller groove spacing, or larger $\beta$. Angular dispersion may be converted to linear dispersion along the exit focal plane of the monochromator by simply multiplying by the focal length ($f$) of the monochromator. The spectral bandpass ($\Delta\lambda_n$) in wavelength units is then determined by dividing the slit width of the monochromator by the linear dispersion. So $\Delta\lambda_n$ gets smaller (higher resolution) for larger $f$, larger order, larger $\beta$, smaller $d$, and smaller slit width. A typical plane grating is operated in the first order. The groove density of the grating might be as high as 3600 grooves/mm, so the groove spacing ($d$) might be as small as 0.0003 mm. Therefore, assuming $\beta = 45^\circ$ and the slit width is 25 $\mu$m, a monochromator with a focal length of 500 mm provides a spectral bandpass of 0.01 nm. Such a system effectively isolates most ICP emission lines. Simultaneous multielement determinations are not performed effectively with such a system, however. The focal plane for this type of monochromator is 5-cm long at best, so the entire spectral window is approximately 20 nm in width. Unless the analyte of interest exhibits emissions lines within 20 nm of one another, the wavelength must be scanned to detect multiple elements. So, two other optical approaches have become more popular for simultaneous determinations: the concave grating placed on a Rowland circle, and the echelle grating coupled with a prism order-sorting device.

Shortly after designing his grating ruling engine in 1881, Rowland first conceived the idea of ruling gratings on a spherical mirror of speculum metal. The most important property of such a concave grating was also observed by Rowland. If the source of light and the grating are placed on the circumference of a circle, and the circle has a diameter equal to the radius of curvature of the grating, then the spectrum is always brought to a focus on the circle. Hence, the focal “plane” is curved, and of considerable length (Figure 5). In this case, one entrance slit is placed on the circle for introduction of the source radiation, and multiple exit slits may be placed around the circle at the analytical wavelengths of interest. Hence, Rowland’s circle is ideally suited for multielement ICP emission spectrometry. A further advantage of the Rowland geometry is the elimination of the need for any collimating or focusing lenses or mirrors. A Rowland circle spectrometer with the same groove density, slit width, and focal length as the plane grating system described above, provides similar spectral bandpass but with a much larger spectral window.

The echelle grating is a coarsely ruled grating, typically having a groove density of 70 grooves/mm, so $d = 0.014$ mm. The increase in spectral bandpass due to the increase in $d$ is overcome by operating the echelle grating in higher orders ($m = 25–125$) and by using steeper angles of diffraction ($\beta > 45^\circ$). Figure 6 demonstrates how the steeper sides of the groove facets are used with the echelle grating. If the steep sides of the grooves are blazed such that specular reflectance occurs when $\alpha = 60^\circ$ and $\beta = 50^\circ$, then each wavelength exhibits a peak in grating efficiency at a particular order as determined by the grating formula. For example, for the 70 grooves/mm echelle grating described above, the order of maximum efficiency ($m_{\text{max}}$) occurs as shown in Table 4. The efficiency of the echelle grating for a given wavelength at its optimum order can be as high as 65%. This level of efficiency is typically attained across the free spectral range for a given order. The free spectral range ($\Delta\lambda_n$) is defined as the range of wavelengths over which no overlap from adjacent orders.
occurs, and is given by Equation (7):

$$\Delta \lambda_f = \frac{\lambda}{m + 1}$$

(7)

As indicated in Table 4, $\Delta \lambda_f$ is very small for large values of $m$. Obviously, then, severe spectral overlap occurs with an echelle grating. The overlap does not simply involve adjacent orders, but all orders are dispersed in multiple layers along the same focal plane. This overlap is corrected most often with an order-sorting prism. This prism is placed between the echelle grating and the focal plane (Figure 7). The prism is positioned so that it disperses the light in a direction perpendicular to the direction of dispersion of the grating. As a result, the focal plane has wavelength dispersed in the horizontal direction and order sorted in the vertical direction. The free spectral range (and the region of maximum efficiency) has a roughly triangular shape centered horizontally on the plane (Figure 8). An echelle monochromator often provides a spectral bandpass nearly 10 times smaller than that of a typical grating monochromator with a similar focal length. In addition, the echelle system provides high efficiency at many wavelengths rather than a single blaze wavelength. Finally, both the high efficiency and superior resolution are available over a very broad spectral window. As a result, the echelle configuration is the predominant optical arrangement in modern ICP-OES instruments.

5.2 The Photomultiplier Tube

Figure 9 is a schematic representation of the PMT. Like its predecessor, the vacuum phototube, the heart of the PMT consists of two electrodes sealed in a fused-silica envelope. The cathode has a relatively large surface area, usually in the shape of a vertical, hollow “half cylinder”. The cathode is made from a photoemissive material such as an alkali metal oxide. The anode is simply an electron collection wire or grid. Unlike the phototube, however, the PMT has up to 14 secondary emission dynodes placed between the cathode and the anode. Typically, the anode is fixed to the ground potential and the dynodes are at potentials that are successively more negative, by about 100 V/dynode. The potential of the cathode is typically $-1000$ V.

A photon generated in the ICP and passing through the wavelength selection device may pass through the fused-silica envelope of the PMT, through a baffletype grill, and strike the photocathode. If the energy of the photon is higher than the work function of the photocathode material, then an electron may be ejected from the cathode. The fraction of photons with energy greater than the work function that actually produce a photoelectron is called the quantum efficiency of the...

### Diagram

**Figure 8**  Diagram representing the two-dimensional focal plane provided by the echelle polychromator (a). The triangle-shaped free spectral range is the region of highest grating efficiency. The distance between adjacent vertical lines is 1 nm, and the beginning ($\lambda_1$) and ending ($\lambda_2$) wavelengths depicted by the lines are listed for each order. Only 1 out of every 10 orders is shown for clarity. An actual negative image collected during the aspiration of tap water (b) shows atomic emission lines as dark spots against a white background. Close inspection reveals the different orders as faint horizontal lines across the image, with the roughly triangular shape of the free spectral range. An image for distilled, deionized water (c) may be subtracted from the tap water image resulting in a background-subtracted image (d). The region of interest may be enlarged so that emission lines from Ca, Mg, and Si in the tap water may be identified (e).
ATOMIC SPECTROSCOPY

\[ G = x^n \]  

where \( n \) is the number of dynodes. The gain depends upon the voltage across the PMT and it may be as high as \( 10^8 \). One of the best features of the PMT is that the gain is acquired with almost no increase in noise. Thus, the PMT is ideally suited for the detection of small analytical signals against a relatively dark background, as is the case near the detection limit in high-resolution atomic emission spectrometry.

Usually the entrance aperture, as defined by the grill on the PMT, is very large compared to a single resolution element at the focal plane of a monochromator. This disparity is corrected by placing a mechanical slit on the focal plane in front of the PMT. The width of this slit then defines the range of wavelengths (\( \Delta \lambda \)) that are allowed to strike the PMT. Sequential detection of multiple elements can be accomplished by changing the grating angle in a conventional monochromator, thus scanning the wavelengths that are detected. A second approach is to move the PMT rapidly along the focal curve of a Rowland circle spectrometer. Such a spectrometer may have several prealigned exit slits along the focal curve, each corresponding to a particular element (Figure 5). A still more efficient method for sequential multielement determinations involves the echelle polychromator (Figure 7). A mask with many slits, each corresponding to a different element, may be placed upon the two-dimensional focal plane. The PMT is held in a mechanical arm that quickly positions the detector at the appropriate \( x-y \) coordinates for a given element. This design allows very fast sequential determinations by “wavelength hopping” or direct reading rather than scanning linearly through all wavelengths to reach a select few. One commercial instrument using this design is called a direct reading echelle (DRE) ICP instrument.

Simultaneous multielement determinations may be performed with multiple PMTs, but such designs quickly become limited by the size of the PMTs and the geometry of the polychromator. Multiple PMTs may be positioned either along the focal curve of a Rowland circle spectrometer or along the exit plane of an echelle polychromator. Solid-state detectors, with their relatively small size and their intrinsic multielement nature, are usually more effective for simultaneous determinations.

5.3 Array Detectors

Charge transfer devices (CTDs) include a broad range of solid-state silicon-based array detectors.\(^{141}\) They include the charge injection device (CID) and the charge-coupled device (CCD). The CCD has found extensive use in nonspectroscopic devices such as video cameras, bar code scanners, and photocopiers. With the CTDs, photons falling on a silicon substrate produce electron–hole pairs. The positive electron–holes migrate freely through the p-type silicon semiconductor material, while the electrons are collected and stored temporarily by an array of metal oxide semiconductor (MOS) capacitors (Figure 10). Each
MOS capacitor is composed of a small metal electrode and a thin layer of insulating SiO₂ material on top of the p-type silicon substrate. A positive potential is applied to the metal electrode, so the electrons generated in a given region are trapped just below the insulating layer. Each MOS capacitor (or pixel) has a width in the 5- to 50-µm range and a height that may be as large as 200 µm. A two-dimensional array of pixels is easily prepared by proper placement of the metal electrodes. Such arrays may vary in size, even beyond 4000 pixels on an edge. The CCD differs from the CID mainly in the readout scheme. The CCD is read out in a sequential charge shifting manner toward the output amplifier. The CID, on the other hand, may be read out in a nondestructive manner by shifting charge between adjacent electrodes, and then shifting it back again. The CID thus benefits from quick random access, even during long integration periods.

Spectroscopic applications of CTDs have been hampered by the physical mismatch between the relatively small surface area of the detector and the large, sometimes two-dimensional, focal plane associated with polychromators. This mismatch may be overcome, however, and one commercial ICP spectrometer employs a CID detector having more than 250,000 pixels positioned upon an echelle focal plane.

Alternative approaches have been successful with the CCD detector. In one case, a group of several CCD arrays are arranged around a circular optical system (CIROS) based upon a Rowland circle design. Rather than monitoring discrete wavelengths, as is the case with the multiple PMT Rowland circle systems, the CIROS system provides total wavelength coverage from 120 to 800 nm, with resolution on the order of 0.009 nm.

A second multiple CCD array detector has been available commercially. This detector, called a segmented array charge-coupled device detector (SCD), employs over 200 small subarrays of 20–80 pixels each. The subarrays are positioned along the two-dimensional focal plane of an echelle polychromator. The position of each subarray corresponds to one of the 236 most prominent ICP emission lines of the most commonly determined 70 ICP elements. This design allows for discrete wavelength determinations as seen with the multiple PMT designs, but it also provides additional spectral information around the vicinity of each emission line without exhaustively recording data at all wavelengths.

Another approach to correcting the mismatch between conventional imaging CTD arrays and the focal plane of an echelle spectrometer is to specifically design a CTD array to exactly match the spectrometer image. This process, called image-mapping the detector or large format programmable detection, is available in a couple of commercial products. One device called the VistaChip consists of a series of 70 diagonalized linear arrays (DLAs) of pixels that are designed to exactly match the individual diffraction orders present in the focal plane of the echelle spectrometer. The 70 DLAs correspond to orders 19–88, and the length of an individual DLA is set to match the free spectral range for the corresponding order. In this fashion, continuous wavelength coverage is provided across the range 167–363 nm, and selected coverage is provided in the range 363–784 nm where the diffraction orders are wider than the selected width of the detector (although no atomic emission lines of relevance miss the detector). The overall dimensions of the VistaChip are 15 × 19 mm, and a total of 70,908 pixels are packed inside the 70 DLAs. Other commercial CTD detectors are now as large as 27 × 27 mm, and any wavelength point on the chip may be accessed, from 160 to 1100 nm. As a result of this broad spectral coverage, the combination of echelle polychromator and CTD has become the system of choice for ICP-OES.

5.4 Simultaneous versus Sequential Detection

In the final analysis, the detection system most appropriate for an ICP emission system depends upon the application. In cases where only one or two elements are determined routinely, the traditional scanning sequential detection system may be sufficient. The high sensitivity provided by a PMT coupled with the flexibility of interrogating any wavelength region may outweigh the need for rapid determinations. On the other hand, if the application may vary between the determination of a few elements to the determination of many, the reasonable cost and high sensitivity of the PMT-based direct reading systems may be attractive. Finally, if a large suite of elements must be determined on a routine basis, one of the array-based detection systems might be most suitable.

6 ANALYTICAL PERFORMANCE

6.1 Analytical Wavelength

The ultraviolet and visible regions (160–800 nm) of the electromagnetic spectrum are most commonly used for analytical atomic spectrometry. In ICP-OES, the number of elements that can be determined is related to the wavelength window that can be covered by the optical system. With current echelle-CTD combinations, this entire spectral window may be surveyed simultaneously (Figure 8). For the tap water sample image in Figure 8(b), note the relative crowding of the emission lines in the visible region (in the bottom third of the image). In this negative image, individual emission lines due to elements in the sample appear as dark spots against a white background. Many of these spots may also arise
from Ar emission lines, and hence are clustered in the visible region. In addition, the continuum emission from the plasma is relatively intense in the visible region, as evidenced by the gray shading across this region. These emission signals arising from the background may be effectively corrected by subtracting a blank: the image of a distilled-deionized water sample (Figure 8c). The resulting corrected spectrum (Figure 8d) shows only those lines due to the elements present in the tap water but not in the blank. Upon expansion of the region of interest marked by a rectangle in Figure 8(d), one may identify the metals of interest in the sample (Figure 8e). In this case, multiple lines are observed for both Mg and Ca. As a rule of thumb, in the absence of significant interferences, wavelengths above 500 nm are employed when alkali metals need to be determined, whereas wavelengths below 190 nm or even below 160 nm are employed when elements such as chlorine, bromine, nitrogen, or arsenic must be determined. There are several criteria for selecting the specific analytical lines for analysis. First, the wavelengths must be accessible by both the dispersive system and the detector. Second, the wavelengths must exhibit signal levels appropriate for the concentrations of the respective elements in the sample. Third, the wavelengths selected must be free from spectral interferences. When this is not possible, emission lines whose intensities can be corrected to account for spectral interferences should be chosen. Fourth, if an internal standard scheme is used, it may be preferable to match the analyte ion lines with an internal standard ion line, and analyte neutral atom lines with an internal standard neutral atom line. Most modern instruments offer several wavelength suggestions for each element, and they are capable of simultaneously monitoring multiple lines for a single element to reduce the potential for interference.

6.2 Quantitative Methods

The calibration curve method using aqueous standard solutions is easily employed in ICP-OES. Aqueous stock solutions for single metals or aqueous mixtures containing multiple metals are available from several commercial vendors. In addition, stock solutions may be prepared in the laboratory with little difficulty.\(^{43}\)

In those cases where the analytical signal is noisy owing to variations such as small changes in solution flow rates, gas flow rates, or plasma position, the internal standard method may be employed. The internal standard element may just as easily be added to each solution by the analyst. The choice of the internal standard element may be critical. The element should not be present in the sample type of interest, should not interfere spectrally with any of the analytes of interest, and in the best case should have physical and chemical properties similar to those of the analyte.\(^{44}\) The perfect internal standard element experiences the same matrix effects and spectral background as the analyte. In practice, many internal standard elements are suitable, and published analytical procedures may offer a suite of choices for a given analyte. In some cases, a single internal standard could be effective for a large number of different analyte elements. This approach is most successful under robust ICP conditions: high ICP power (\(\sim 1.5\ kW\)) and low carrier gas flow rate (\(\sim 0.6\ L\ min^{-1}\ Ar\)).\(^{45}\) The procedure is straightforward. One simply adds the internal standard element with a constant concentration to each standard and sample solution to be analyzed. For example, a Pb calibration curve in the range of 0–100 ng mL\(^{-1}\) may be constructed by preparing 5 Pb standard solutions spanning this concentration region, each containing 100 ng mL\(^{-1}\) Cu. The Pb emission line at 217.0 nm may be monitored along with a nearby Cu emission line at 216.5 nm (Figure 11). If spectra such as this are collected for each solution, a plot of the raw Pb signals generate the calibration points depicted by the black diamonds in Figure 12. If on the other hand, those same Pb signals are divided by the emission signal for Cu in each spectrum, a better linear fit is observed (circles in Figure 12). When the curves are scaled to the same magnitude, note that the slopes are nearly identical, since, in theory, the internal standard plot is equivalent to the raw plot divided by a constant. In this example, not only is the linear fit improved but the signal-to-noise ratio for the individual measurements is increased by nearly a factor of 10.

In extreme cases, where the sample matrix actually affects the slope of the calibration curve, the standard addition method should be employed. Urine samples have been analyzed by ETV-ICP-OES after simple 1:1 dilution with water by this technique.\(^{46}\) The urine sample was divided into five separate 1-mL aliquots. Successively, greater amounts of a Cd standard solution were added to

![Figure 11 ICP-OES spectrum of a solution containing 60 ng mL\(^{-1}\) Pb and 100 ng mL\(^{-1}\) Cu.](image)
the five aliquots, resulting in a series of solutions having 0, 2.5, 5.0, 7.5, and 10.0 ng mL\(^{-1}\) added Cd. Each solution was also spiked with 1 \(\mu\)g mL\(^{-1}\) Bi as an internal standard, and the final volume was made up to 2 mL with water. No further sample preparation was employed, and the ETV-ICP-OES signals from Cd (diamonds) and Cd/Bi ratio (circles) are plotted in Figure 13. Note that the internal standard correction is necessary to improve the fit such that an accurate \(x\) intercept may be determined. The value for the \(x\) intercept is \(-1.1\) ng mL\(^{-1}\), and thus the original urine sample was found to contain \(1.1 \pm 0.2\) ng mL\(^{-1}\) Cd. Analysis of the same sample by GFAAS following microwave acid digestion gave a value of \(1.3 \pm 0.5\) ng mL\(^{-1}\) Cd.\(^{[46]}\)

6.3 Analytical Figures of Merit

For ICP-OES, the analytical figures of merit include the number of elements that can be determined, selectivity, reproducibility, long-term stability, susceptibility to matrix interferences, LOD, and accuracy.\(^{[47]}\) The number of elements that can be measured by ICP-OES is often more than 70 out of a total of 92 naturally occurring elements, as listed in Table 5. Routine determination of 70 elements can be accomplished by ICP-OES at concentration levels below 1 mg L\(^{-1}\). As can be seen from Table 5, almost all naturally occurring elements, with the

</table>
exception of hydrogen, oxygen, fluorine, and inert gases, can be determined by ICP-OES. The elements that are not usually determined by ICP-OES fall into three basic categories. The first category includes those elements that occur as trace contaminants in the argon gas used in the ICP-OES (C from CO₂, constituents of the sample solvent (C, O, H), or as contaminants from the environment or atmosphere (N, for example). The second category encompasses those elements that require high excitation energy, such as the halogens. These elements could be determined with poor LOD, however. The third category is the family of short-lived radioactive elements that are commonly determined by γ-ray spectrometry.\(^{(1)}\)

Selectivity is important to minimize the spectral overlap interferences resulting from elements with rich line-emission spectra (tungsten, cobalt, niobium, molybdenum, tantalum, and rare earth elements) and to improve the signal-to-background ratio (SBR).\(^{(47)}\) Selectivity is largely decided by the practical resolution of the wavelength dispersive system of the ICP-OES instrument. High selectivity is usually achieved with a sacrifice in sensitivity and the wavelength coverage range. For the best commercial ICP-OES instruments, a resolution of less than 5 pm is possible.\(^{(45)}\)

The LODs of ICP-OES are generally in the nanogram per milliliter range. The LOD is usually defined as the analytical concentration that produces an analytical signal equivalent to three times the standard deviation observed for 16 measurements of a blank solution.\(^{(48)}\) Another definition for the LOD of ICP-OES is related to the SBR of the analyte line at a given concentration, \(c\), and the relative standard deviation (RSD) of the background, \(\text{RSD}_B\) as shown in Equation (9)\(^{(49)}\):

\[
\text{LOD} = \frac{3 \times c \times \text{RSD}_B}{\text{SBR}}
\]  

The LOD is determined, therefore, by the sensitivity of the measurement and the noise level, or stability, of the ICP-OES instrument. The high degree of stability of an ICP was identified when Greenfield et al.\(^{(10)}\) first used an ICP for analytical atomic spectrometry. For the best ICP-OES instruments, a long-term stability of less than 1% RSD has been achieved.\(^{(47)}\) The atomic emission signals from the ICP are larger than those from other sources, such as a flame. This occurs because the high-temperature and inert-argon environment of the ICP leads to more efficient atomization, ionization, and excitation. In fact, the temperature of the ICP is so high that the largest signals are usually from the ionic lines. There are many other factors that may influence LOD, such as nebulizer type, view mode, and sample matrix.\(^{(50,51)}\) Table 6 shows representative ICP-OES LODs obtained for 27 different elements.\(^{(3)}\) LODs using an axially viewed plasma are typically better than those observed by radial viewing by a factor of 5–10\(^{(1)}\) as shown in Table 6. Table 7 shows LODs for ETV-ICP-OES in comparison with those of GFAAS. LODs for many elements by ETV-ICP-OES are better than or equivalent to those achieved by GFAAS.\(^{(52,53)}\) Notice that some elements that cannot be determined by GFAAS can be measured by ICP-OES.

Often the background equivalent concentration (BEC) is also used to check instrumental performance in ICP-OES. The BEC is defined as the concentration of a solution that results in an analyte emission signal equivalent in intensity to that of the background emission signal at the measurement wavelength. The BEC can be used as an indicator of relative sensitivity for an emission line. An unusually high BEC often indicates problems with the efficiency of the sample introduction system.

The LDR of calibration curves for ICP-OES is usually 4–6 orders of magnitude wide, starting from the LOD on the low-concentration side. These LDRs are significantly larger than the 2–3 orders of magnitude observed for competing techniques such as AAS and arc/spark OES. The wide LDRs in ICP-OES translate into simple preparation of calibration curves. Very often,

---

NA, not available.

a single standard together with a blank solution is enough to produce an accurate calibration. Multiple sample dilutions are seldom needed prior to the analysis.

In general, the accuracy of the ICP-OES technique gets poorer as the analyte concentration approaches the LOD. For semiquantitative analysis (accuracy ±10%), the analyte concentration should be at least five times higher than the LOD. For accurate quantitation (±2%), the concentration should be 100 times greater than the LOD. At this concentration level, the precision is typically better than 1% RSD. This precision is considered sufficient for most trace element determinations. Better precision can be achieved, if necessary, by sacrificing analysis speed or with a more complex instrumental design. The concept of limit of quantitation (LOQ) has been defined as a concentration for which the precision, expressed as RSD, would be below a given threshold, for instance, 10 or 5%.\(^{54}\) A 5%-based LOQ normally occurs at concentrations approximately 10 times greater than the LOD (based upon three standard deviations).

### 6.4 Interferences

Among all commonly used analytical atomic spectrometry techniques, ICP-OES is probably the one with the fewest number of interferences. The argon plasma is inert when compared to the chemical reactivity of a flame. Also, the high temperature of the plasma helps to reduce chemical interferences. The temperature is high enough to break down most species into atoms or ions for excitation and subsequent emission. In contrast, in a low-temperature flame, chemical interferences can be a severe problem. For example, a small amount of aluminum will interfere with the determination of calcium in flame AAS, but even at aluminum concentration 100 times higher than this, interference is not observed in ICP-OES. However, chemical interferences do exist in the ICP. Sometimes higher RF power and/or lower inner argon flow rates are used to reduce these interferences. One particular type of chemical interference is the so-called easily ionized element (EIE) effect. The EIEs are those elements that have low ionization potentials, such as alkaline elements. High concentrations of EIEs can suppress or enhance emission signals, depending upon the analyte species. One way to reduce the EIE effect is to dilute the sample solution to the point that the EIE effect is not measurable. Sometimes, higher RF power or mathematical correction may be used to compensate for EIE interference. Instrumental conditions such as slit width, viewing height, and viewing volume can be chosen to minimize interference and to optimize emission signal collection in either axial or radial configuration.\(^{55}\)

The most common interference problem in ICP-OES is spectral interference (also referred to as background interference). Ironically, this type of interference arises because of the multielement nature of the plasma. Since the ICP is capable of exciting almost any element that is introduced into the plasma, spectra are likely to be rich, especially for highly complex and concentrated samples. The solution to the spectral interference
problem, as discussed previously, is the use of high-resolution spectrometers. Some spectral overlap may even exist with the best commercial system. In these cases, advanced background correction techniques are employed or a different analytical wavelength for the element(s) of interest is chosen. Spectral interferences can be categorized into four categories: simple background shift, sloping background shift, direct spectral overlap, and complex background shift. The simple background shift is defined as a shift in background intensity that is essentially constant over a given wavelength range on either side of the analytical line. The background may shift up or down. There are two approaches to deal with this background problem. The first is to select a different analytical line at a wavelength with no background interference. The second is to correct for the background by measuring it somewhere near, but not falling on, the profile of the analytical line of the analyte element. Two background correction points, one on each side of the profile of the analytical line, are used to correct for the sloping background shift. This means that the average signal measured at the two points is subtracted from the total signal measured at the analytical line. In the worst case, direct spectral overlap occurs. This can be corrected if the magnitude of the interference is known as a function of the concentration of the interfering element. A correction factor can be calculated and used to correct the signal measured at the analyte wavelength. This can be best achieved by making simultaneous measurements of both the signal at the analyte wavelength and at a different wavelength for the interfering element. This method is referred to as the concentration ratio method or inter-element correction method. The basic requirement is that the concentration of the interfering element can be accurately measured at another wavelength. With advanced detector systems, all spectral lines are present, so IEC is possible. A complex background shift is a shift in a background intensity that varies significantly on both sides of the analytical line. This is usually caused by the occurrence of a number of intense, closely spaced emission lines nearby, and perhaps directly overlapping the analyte wavelength. In this case, a different analytical wavelength should be chosen if possible.\(^1\)

**ACKNOWLEDGMENTS**

This work was funded in part by Teledyne Leeman Labs, Hudson, N.H. Teledyne Leeman Labs also provided the photograph in Figure 1, and the schematics in Figures 3 and 7. The images in Figure 8 were acquired with a Prodigy ICP-OES system provided by Teledyne Leeman Labs as well.

Laser ablation (LA) is a unique technique to transform a solid sample into vapor-phase constituents, which can be chemically analyzed by atomic spectroscopy. Ablation brings many exciting capabilities to the field of chemical analysis, primarily because of the laser-beam properties. The ability to analyze directly any solid sample without sample preparation and minimal sample-quantity requirements are just some of the unique capabilities. This article discusses current issues related to using LA in atomic spectroscopy. A general introduction to LA sampling is presented along with a comparison with other solid sampling techniques. The critical issues for all analytical techniques are calibration, accuracy, and sensitivity. Techniques that have been demonstrated to address these analytical characteristics and define these parameters for LA are investigated in detail. Finally, many unique applications are described, ranging from dating geological materials to providing crime-scene evidence. Most of these applications could not be performed without the use of a laser beam. The inductively coupled plasma (ICP) will be emphasized in this article because it is currently the most prevalent excitation and ionization source for chemical analysis using LA.

1 INTRODUCTION

Want to know the composition of an unknown solid sample? Don’t want to deal with acids, wastes, and laborious procedures to conduct the analysis? What is the best way to transform the unknown solid sample into vapor-phase constituents for chemical analysis? The answer: explode the sample with a high-power laser beam! This is precisely the role of LA in atomic spectroscopy. Complex solid samples, including environmental wastes, geochemical materials, coatings, extraterrestrial samples, and others dictate the development of a sampling approach for chemical analysis that does not rely on complicated, laborious dissolution procedures; a direct approach for analyzing unknown samples has been a quest of analytical chemistry for a long time. In some cases, the desire is to analyze a sample chemically without destruction, especially if that sample is the Shroud of Turin! These are some of the characteristics that make ablation sampling attractive for atomic spectroscopy. This article will discuss current issues related to LA in atomic spectroscopy, including calibration and optimization, accuracy, sensitivity, and particle transport. In addition, many unique applications will be described, in some cases applications that cannot be performed without the use of a laser. The ICP is emphasized in this article because it is the most prevalent excitation and ionization source for chemical analysis using LA at this time.

1.1 Characteristics of Laser Ablation

One of the most unique characteristics of LA is that any solid sample can be directly ablated into vapor-phase constituents (vapor and particles), be it a rock, hair sample, extraterrestrial sample, or priceless piece
of artwork. Only a very small portion of the sample is required for the analysis – sometimes of the order of picograms or less. Damage at these levels is generally not visible without the use of a microscope. In addition, there is no requirement for sample preparation; the laser beam can be used to ablate the surface contamination, as well as dig a crater and provide bulk analysis.

Because the laser beam directly converts the solid sample into the vapor phase, liquid reagents are not required to digest the sample. Therefore, there is no solution waste, no worries about loss of volatile species, and minimal sample handling. In addition, when liquid sample introduction is used, a larger portion of the sample is required because of dilution. Another significant and unique advantage of LA is the ability to perform spatial (micrometer) characterization. Since the laser beam can be guided to an exact location on a surface, the analyst can choose where the explosion and, therefore, the sampling occur. If the sample of interest is the microscopic inclusions in a bulk material, or particles on a filter paper, it is not necessary to analyze the entire sample; most of the mass in this case is not related and leads to large background signals in the analytical source. Finally, if one wants the analysis performed immediately, LA is the way to go – there are no time-consuming sample preparation or dissolution procedures; just place the sample in a simple chamber and hit it with the laser beam. With capabilities and advantages such as these, LA atomic spectroscopy is now utilized routinely in many industries, using commercially available and laboratory-built systems.

1.2 Solid Sampling Techniques: Comparison

The development of any “new” technique for elemental analysis requires parameters such as sampling, excitation, ionization, and detection to be critically investigated and optimized. An “ideal” sample introduction technique has to satisfy certain criteria, which include:

- remove a sufficient quantity of sample;
- reproducible sampling;
- minimal interference on the performance of the detection system;
- sampled material must be representative of the bulk composition (stoichiometry);
- absence of matrix effects (no variation of analyte signal in different matrices);
- sample transport to the excitation or ionization source without losses;
- absence of memory effects and sample carryover;
- adjustment of sampling parameters to satisfy detection requirements.

Among the most popular direct solid sampling methods are LA, glow discharge (GD), and spark/arc ablation. Direct analysis of solids with GD sources has been used with both atomic emission and mass spectrometric detection. GD converts a solid sample directly into the atomic phase by sputtering processes. Because sputtering is a primary sampling mechanism, heating is minimal and preferential vaporization is minimized. GD is best suited for conductive samples, although nonconductive samples can be analyzed with a radiofrequency discharge. A GD source coupled to a high-resolution mass spectrometer is a powerful technique for achieving excellent depth profiling and detection characteristics with a limit of detection (LOD) in the range 10–100 ng g\(^{-1}\).

For arc/spark ablation, mass is eroded from the sample in the form of atoms, molecules, vapor, droplets, solid flakes, and large particles. Normally, only conductive samples can be used with a spark discharge; however, nonconductive materials can be analyzed by mixing the sample with a conductive matrix.

Because of unique benefits and capabilities for direct solid sampling, LA has outpaced development of these other techniques. Laser sampling has been employed with flame and graphite furnace atomic absorption spectroscopy, with typical LODs in the micrograms per gram range. A description of these methods can be found in a review by Darke and Tyson.\(^1\) The direct current plasma (DCP) and microwave-induced plasma (MIP) have been used for the analysis of solid samples with LA sampling.\(^2,3\) The DCP and MIP offer good detection limits in the micrograms per gram range, with linear calibration curves over several orders of magnitude of concentration.

The ICP has become the prevalent source for chemical analysis with LA sampling.\(^4\) The ICP plasma is robust, with high temperature and electron number densities, and is in most cases unperturbed by small amounts of sample. A separate article (Inductively Coupled Plasma/Optical Emission Spectrometry) is dedicated to the ICP. Slurry nebulization of powders, electrothermal vaporization (ETV), direct sample introduction (DSI), spark/arc and LA techniques are among the most popular methods investigated for solid sampling into the ICP. Each of these techniques has unique features: sensitive analysis of powders (slurry nebulization, ETV); analysis of small volumes of solids and liquids with selective solvent or matrix removal (ETV); direct sampling and atomization in the ICP plasma (DSI); analysis of conductive samples (spark ablation); and analysis of any sample (LA). A comparison of slurry nebulization, ETV, and LA methods was reviewed by Darke and Tyson.\(^5\) DSI for ICP was recently reviewed by Sing.\(^6\)
2 FUNDAMENTAL CHARACTERISTICS

Because of the numerous capabilities and advantages for atomic spectroscopy, there is a tremendous demand to understand fundamental LA processes. LA is complex, consisting collectively of many nonlinear mechanisms, each operative on different timescales, from femtoseconds to seconds. When the laser beam irradiates the surface, electrons will be released on the femtosecond to picosecond timescales, followed by atomic and molecular mass on the nanosecond timescale, and then the eruption of large particles, microseconds after the laser pulse has ceased (Figure 1a–c). With different processes occurring over so many orders of magnitude in time, it is no wonder the collective phenomena have never been combined into a unifying theory. However, it is critical to point out before discussing fundamental issues that LA sampling is easier than liquid nebulization. In fact, there have been many years of science devoted to proper dissolution procedures in order to achieve accurate analysis – and still one must be very careful when dissolving a sample that is truly ‘unknown’. The underlying fundamentals of LA should not preclude its development as the method of choice for direct solid sampling in atomic spectroscopy.

Studying fundamental LA mechanisms will provide further improvements and benefits for atomic spectroscopy. By understanding ablation, it will be possible to control process variables, such as the ability to couple the laser beam efficiently into the sample, ablate a reproducible quantity of mass, control the amount of mass ablated, minimize preferential ablation, produce stoichiometric ablation, and control the particle size distribution. By controlling these variables, LA in atomic spectroscopy will become a routine chemical analysis technology for environmental, health, forensics, nonproliferation, and other applications where the primary sample is in the solid phase.

2.1 Ablation Processes

Many studies have been dedicated to understanding fundamental ablation mechanisms. Research studies have shown that LA of a solid sample consists of several stages, in which different kinds of ‘vapor products’ are ejected. The initial stage is electronic excitation inside the solid, accompanied by ejection of electrons at the sample surface, due to both photoelectric and thermionic emission. During this time, energetic electrons in the bulk of the solid also transfer energy to the lattice through a variety of scattering mechanisms; the sample target then undergoes melting and vaporization, followed by ionization and formation of a plasma plume consisting of the sample constituents. The expanding plume interacts with the surrounding gas to form a shock wave, causing the ambient gas to become further ionized. The expanding high-pressure plasma exerts a force back to the target, which flushes out the melted volume. This recoil pressure and flushing mechanism can produce large-sized particles (several micrometers). There is evidence of explosive boiling, occurring microseconds after the laser is finished, which also can produce micrometer-sized particles. Atomic- and micrometer-sized particles will both be transported to and digested in the ICP. Therefore, it is important to understand mechanisms of atomic- and

Figure 1 LA involves complex and collective phenomenon, exhibiting significant nonlinearity in space and time. The images show the evolution of the laser explosion from a solid surface. (a) At 30 ps after the laser hits the sample, electrons leave the surface and collide with air to form the plasma; (b) at 3 ns, atomic vapor escapes from the surface; and (c) at 3 µs, large (>20 µm) particles are spalled from the bulk.
micrometer-sized particle generation; particles in each of these size ranges can have different chemistries, affecting analytical accuracy. The particle size distribution will also affect transport efficiency and therefore analytical sensitivity.

To achieve accurate LA sampling, the composition of the ablated mass should be the same as the sample composition. To achieve high sensitivity, all of the ablated mass should be transported to and digested in the ICP. There are four primary processes that influence the accuracy and sensitivity in laser ablation/inductively coupled plasma (LA/ICP). The first is the LA process itself. For different laser conditions, the composition and quantity of the ablated mass can change significantly. The particle size distribution and particle composition can also change with laser conditions. The second process is transport, which includes the sample chamber design and tubing used to carry the ablated mass to the ICP. Transport efficiency will be different for different sized particles. The third process is sample digestion and excitation in the ICP. The conditions in the ICP (electron temperature and number density) which are controlled by ICP power, gas flow rate, and height above the load coil will influence vaporization, atomization, and ionization of the analyte. However, the amount and composition of the analyte and the matrix can change the ICP conditions (Figure 2). The fourth process includes detection, using the mass spectrometer for inductively coupled plasma mass spectrometry (ICPMS) or the spectrometer and photon detector for inductively coupled plasma atomic emission spectroscopy (ICP-AES). These processes are discussed separately below as to their influence on accuracy and sensitivity.

2.2 Processes Affecting Accuracy

An expectation of any analytical procedure is accurate analysis; the detected mass composition must be the same as the sample composition. For LA sampling, fractionation (preferential mass removal during LA), which can cause inaccurate analysis, can occur under some conditions. Numerous studies have shown that fractionation can be minimized or eliminated, depending on the sample and laser properties. Fractionation at the sample is a function of wavelength; ultraviolet (UV) LA has been found to provide better stoichiometry than infrared (IR) LA. The number of laser pulses at a fixed location on the sample, the laser irradiance, and laser beam spot size (related to focus position) also influence fractionation (Figure 3). Fractionation at the sample, attempts have been made to correlate ablation behavior with melting, boiling, vapor pressure, atomic or ionic radius, charge, and speciation. Fractionation in alloys depends on the latent heat of vaporization; the higher the latent heat, the more difficult it is to vaporize a constituent. For example, in brass, the latent heat of vaporization of Cu is greater than that of Zn; Zn can be preferentially ablated compared to Cu in these samples. By using a calibrated ICP-AES instrument, fractionation based on thermal vaporization was demonstrated by measuring Zn/Cu mole ratios during ablation of brass. With a 30-ns, 248-nm excimer laser, the Zn/Cu mole ratio initially decreased with increasing laser irradiance, then stabilized at irradiance greater than approximately 0.3 GW cm⁻². The initial decreasing Zn/Cu ratio was due to thermal vaporization. For higher laser irradiance, there are likely several competing mechanisms involved in the ablation processes. Melt flushing from the crater, plasma shielding, and/or radiative heating by the laser-induced plasma can contribute to mass ejection. Picosecond LA is even more esoteric; nonthermal mechanisms must be operative. Using a 35-ps pulse (Nd : YAG, Nd³⁺ : Y₃Al₅O₁₂) laser, some type of nonthermal mechanism appears to govern the LA process because Cu is enriched in the vapor at lower irradiance. The Zn/Cu ratio approaches the stoichiometric value at higher irradiance. These experiments demonstrate
that different mechanisms contribute to fractionation, although identification of the mechanisms is still a large research effort.

Fractionation during transport and/or in the ICP can occur. Fractionation during transport involves selective vapor condensation on the tubing walls or the selective nucleation of species on different-sized particles. These effects are governed by the vapor-phase morphology (droplet/particle shape and size) and chemical composition. Because transport efficiency and chemical composition are particle size dependent, fractionation can occur during transport. Figg et al. demonstrated this effect by inserting a coiled Tygon tube into the transport path; both particle size distribution and fractionation changed significantly. It is believed that many of the large particles come from flushing out the molten liquid layer. The composition of the molten liquid could be significantly different from the bulk because of preferential vaporization and re-deposition from the plasma plume. For “large” particles entering the ICP and undergoing sublimation (vaporization), fractionation may exist in the ICP itself. It is important to state here that fractionation is not a problem that precludes the use of LA for accurate chemical analysis, especially when matrix-matched standards exist. This section was designed to make the reader aware that such issues can exist. There are many applications of LA, as will be discussed in a later section, in which fractionation does not influence the analysis.

2.3 Processes Affecting Sensitivity

The signal intensity in atomic emission spectroscopy (AES) or mass spectrometry (MS) corresponds directly to the quantity of mass ablated and transported to the ICP. Depending on the concentration of the elements in the sample, it may be necessary to increase the quantity of ablated sample to achieve better signal-to-noise ratios. Laser-beam properties (such as wavelength, pulse duration, energy, fluence, irradiance, and temporal and spatial profiles) and the ambient gas influence the quantity of mass ablated per laser pulse.

2.3.1 Laser Energy

The ablated mass can be increased by increasing the laser-beam energy or fluence (energy per unit area). However, the relationship of ablated mass to laser-beam energy or irradiance is not linear. Mass was found to follow a power law with irradiance \( (I)^m \). Using nanosecond laser pulses, with irradiance less than approximately 0.3 GW cm\(^{-2}\), \( m \) had values ranging from 2 to 5 for many samples. When the irradiance was >0.3 GW cm\(^{-2}\), \( m \) became ~1. However, as the irradiance was increased further, another change in the mass ablation rate occurred, in which \( m \) increased to ~2. In the lower irradiance region, thermal vaporization was found to be a dominant process, as evidenced also by fractionation (discussed earlier). In the middle laser irradiance range, plasma shielding may be a major factor governing ablation. The laser-induced plasma formed above the target surface can absorb and/or reflect incident laser energy, thereby decreasing the efficiency of laser energy available for mass ablation.
constant; the final proportion of the laser energy absorbed and transmitted is constant. It is important to point out that this plasma is the basis of another chemical analysis technique, discussed in the article Laser-induced Breakdown Spectroscopy.

In the third irradiance region, mechanisms such as phase explosion and spallation may be dominant. Both crater depth and ICPMS intensity (Figure 4a–c) show dramatic increases at a threshold irradiance of 20–30 GW cm\(^{-2}\). This dramatic change may be caused by explosive boiling.\(^{36}\) The superheated molten liquid can experience an increased fluctuation in its density\(^{37}\) when the temperature and pressure approach the critical point. Near the critical point, this fluctuation can generate vapor bubbles in the superheated liquid. For vapor bubbles larger than a critical radius, bubble growth will occur; bubbles smaller than the critical radius will collapse.\(^{37}\)

Once bubbles of a critical radius have been generated in the superheated liquid, the volume undergoes a rapid transition into a mixture of vapor and liquid droplets. During explosive boiling, rapid expansion of the high-pressure bubbles in the liquid leads to a violent ejection of the molten droplets from the sample. The shadowgraph images of liquid droplets ejected from the silicon surface (see Figure 1a–c) indicate that the onset of the explosive boiling is at an irradiance of approximately \(2.2 \times 10^{10}\) W cm\(^{-2}\).

2.3.2 Laser Pulse Width

Laser wavelength and pulse duration also influence the quantity of ablated mass; the shorter the wavelength and pulse duration, the better the mass removal efficiency.\(^{15,16,23–26,28–30,38,39}\) Using an Nd:YAG laser with a 3-ns pulse duration, the ICPAES intensity was

---

**Figure 4** Crater profiles (a) before and (b) after an explosive boiling threshold. The crater depth changes dramatically from 1 µm to more than 10 µm. (c) ICPMS signal versus laser power density. The ICPMS intensity increases dramatically across the threshold.
found to be almost an order of magnitude greater for UV than IR ablation sampling, with the same fluence. The absolute enhancement was found to be a function of laser irradiance.\(^{(39)}\) When plasma shielding does exist, a lower wavelength is better because there is less absorption by the plasma; more energy is used to remove mass instead of heating the plasma. The shorter the laser pulse duration, the more efficient is the ablation process; picosecond laser pulses provided an order of magnitude greater signal intensity in ICPAES compared with a nanosecond pulsed laser with the same fluence. An explanation for increased mass ablation using picosecond pulses is that plasma shielding may be weaker; more laser energy is coupled to the sample than absorbed by the plasma. Another possible mechanism is that more laser energy is converted to ablated mass instead of being lost in the sample through thermal dissipation, which is a function of pulse duration.\(^{(40)}\) If the pulse duration is femtoseconds, the ablation process should be even more efficient.\(^{(32,33)}\) For femtosecond LA, the generation of vapor and a plasma will occur after the laser pulse is finished. Therefore, there should be no plasma shielding on the femtosecond timescale. Thermal diffusion to the solid also should be negligible. Currently, there are no reports of using femtosecond LA for chemical analysis. However, as femtosecond laser technology becomes more reliable, it is expected that new benefits to chemical analysis (and other applications) will be forthcoming.

2.3.3 Gas Environment

The gas atmosphere in the sample chamber can have a dramatic effect on ablation behavior.\(^{(7,30,31,34,41,42)}\) The use of different gases has been found to enhance sensitivity either by reducing plasma shielding or by influencing the ablated particle size distribution. With He in the ablation chamber, the mass ablation rate was 2–5 times and 10 times greater than that with Ar in the chamber for nanosecond and picosecond laser pulses, respectively.\(^{(13,43)}\) He and Ne provided an increased mass ablation efficiency compared with a decrease with Xe and Kr, relative to Ar for the nanosecond-pulsed LA. The enhancement or depression was found to be dependent on the laser irradiance. For picosecond LA sampling, only He provided an enhancement; there was very little influence on the mass ablation behavior by the other noble gases.

3 ANALYTICAL CHARACTERISTICS

A typical experimental system for LA sampling with the ICP is shown in Figure 5. In general, mass ablated from a target surface inside the sample chamber is entrained into an Ar gas flow and transferred into the ICP source, where particles are first vaporized and then atomized and ionized. In most cases, the sample chamber is placed on a motorized or manually controlled micrometer translation stage. This is especially convenient for the analysis of heterogeneous samples, where different areas on a sample surface are to be analyzed. The individual components are described separately below.

3.1 Ablation Chamber and Transport Tubing

Various types of chambers have been described in the literature; a summary can be found in a review by Moenke-Blankenburg.\(^{(44)}\) Typically, the sample is placed inside a chamber. However, there are cases in which the sample itself was the bottom of the chamber.\(^{(45)}\) The simplest chamber can be a glass tube with two ports for gas flow, and a quartz window (or other transparent material at the laser wavelength) for laser beam delivery. Argon gas flow dynamics inside the chamber play a significant role in particle entrainment. With laminar flow in the chamber, entrainment efficiency and thus detection characteristics are improved; turbulent flow contributes to losses by trapping particles in stagnant flow regions.\(^{(46)}\) The volume of the chamber is an important parameter; a larger internal volume can lead to sample dilution and memory effects. Because LA processes are transient in nature, larger chamber volumes may be advantageous for signal averaging during repetitive sampling experiments. Another important parameter is chamber length; if the laser beam window is located too close to the sample surface, vapor deposition can occur, reducing transmission and therefore the laser energy. Another issue concerning the chamber length is that different times are required for particles of different sizes to be entrained by the flow; larger particles will travel further before becoming entrained.\(^{(47)}\) Depending on the flow velocity inside the chamber, large particles can be lost owing to collisions with the walls before entrainment.

Dispersion of different-sized particles in the ablation chamber depends on the Ar gas flow velocity in the chamber and can contribute to broadening of signal peaks (recorded during single laser pulse experiments). Further dispersion of ablated particles in the transport tube can occur and depends on the transfer tube length and internal diameter. To minimize dispersion, a short, narrow tube should be used. Although particle dispersion in the chamber and transport tube may be important for analysis during single laser pulse experiments, there are no significant advantages to using a short tube during LA sampling with repetitive pulses.
3.1.1 Mass Transport Efficiency

For a given ablation chamber/tube configuration, particle transport efficiency depends on the ablated particle size distribution. The number of particles and their size distribution depends on the laser and sample properties.\(^\text{(22,47,48)}\) The volume distribution of laser-generated particles changes with respect to the laser wavelength; there are more large particles generated with an IR laser than with a UV laser.\(^\text{(48)}\) Since melting and melt-fusing may be responsible for the generation of particles, a thicker molten layer may produce a greater fraction of large particles. The optical absorption depth in most solid samples is greater for IR than UV wavelengths. Therefore, a larger molten liquid volume may be responsible for large particle production using IR LA.

Entrainment of ablated mass into the gas stream and transport to the ICP are particle size dependent. Large particles may not be entrained and those that are may not completely vaporize in the ICP. Particle sizes should be less than about 2 µm for efficient transport to and excitation in the ICP.\(^\text{(45,49,50)}\) Particle entrainment efficiency can be defined as the ratio of mass entering the ICP to the total mass ablated from the sample. Particle entrainment efficiency has been found to decrease with increasing laser irradiance. Entrainment efficiency was about 25% at low irradiance and decreased to about 5% at high irradiance.\(^\text{(47)}\) One possible reason for the small entrainment efficiency at high irradiance may be the formation of excessively large particles (>5 µm); large particle ejection is observed in Figure 1(a–c). The removal of large fractured pieces (>50 µm), possibly due to increased thermal stress and pressure on the sample surface, was also observed after ablation at high irradiances (Figure 6). These very large particles will not be entrained into the argon gas flow, but instead will settle in the ablation chamber due to gravity. Transport efficiency as a function of particle-size distribution needs to be critically studied for improving LA sampling in atomic spectroscopy.\(^\text{(45,51)}\) A few studies have addressed particle transport, with preliminary data suggesting that particles in the 0.1–1.0 µm range reach and vaporize in the ICP.\(^\text{(22,45,48)}\)

Literature values for LA transport efficiency are in the range of about 5–40%.\(^\text{(45,47)}\) The large variation represents the effects of laser beam conditions, sample material properties, and ablation chamber/transfer...
tube geometries. In general, particle losses in the sample chamber and transport tube are mainly due to gravitational settling or inertial impact to the walls for large particles, and diffusion to the walls for smaller particles. These processes depend on the tube length and internal diameter. Transport efficiency for larger particles, which represent most of the ablated mass and thus are responsible for most of the ICP signal, can be improved by utilization of a short, narrow tube. Generally, particles in the range 0.1–1.0 µm are most efficiently transported to the ICP. For a given tubing length and diameter, theoretical calculations predict losses to be flow dependent. In practice, however, no significant differences in the ICPMS signal count rates were observed when the Ar flow rate was varied from 0.1 to 0.9 L min⁻¹ during ablation of Zr metal. Particle losses inside the sample chamber and transport tube can contribute to memory effects. To minimize these effects, it is recommended that the transport tube be cleaned regularly or replaced, and the system flushed with Ar gas at increased flow rates between measurements.

3.2 Laser Systems and Optics

Over the years, several pulsed lasers have been tested for ablation. Ruby (694.3 nm), CO₂ (10.6 µm), free-running Nd: YAG and excimer lasers have been shown to efficiently ablate solid samples. However, Q-switched Nd: YAG lasers with nanosecond pulses have become the most prevalent systems used for LA today. These lasers are relatively inexpensive, easy to operate, and compact, have good pulse-to-pulse and long-term stability characteristics, and deliver sufficient energy for ablation. The fundamental harmonic of 1064 nm can be easily doubled (532 nm), tripled (355 nm), quadrupled (266 nm), and quintupled (213 nm). The Q-switched Nd: YAG laser operated at the fourth harmonic is currently the most popular for LA chemical analysis. Recently, it has been shown that samples with relatively low absorption at 266 nm, such as calcite and garnet, can be more efficiently ablated with the Nd: YAG at 213 nm[52] or the ArF excimer (193 nm).[53]

The laser beam is transferred to the sample chamber by means of mirrors, beam splitters, and/or prisms. In the simplest system, focusing is achieved with a plano-concave singlet lens, which has a low degree of spherical aberration. Laser beam spot size at a sample surface can be easily adjusted by translating the lens relative to the sample. The minimum spot size with radius, w, that can be achieved by focusing a Gaussian diffraction-limited laser beam can be approximated by Equation (1):

$$w \propto \frac{\lambda f}{\pi w_0}$$  (1)

where λ is the laser wavelength, f is the lens focal distance, and w₀ is the initial laser beam radius. By using a lens with a short focal distance and a wide initial beam diameter, the smallest LA spots (best spatial resolution) can be achieved. An optical microscope equipped with a CCD camera is an excellent addition to experimental systems, allowing easy focusing of the laser beam on to a selected sample location, with beam spot sizes in the order of several micrometers. Such systems are widely used, especially for the analysis of geological samples where a high degree of spatial resolution is required.

3.3 Inductively Coupled Plasma Atomic Emission Spectroscopy and Inductively Coupled Plasma Mass Spectrometry Instrumentation

In contrast to liquid nebulization sample introduction, LA sampling is transient in nature. Thus, simultaneous detection of elements is needed. Single-channel instruments equipped with a photomultiplier tube (PMT) require scanning of a monochromator grating. Such systems are not very useful for transient signal detection when detection of more than one element is required. Direct-read polychromators can employ more than 60 exit slits with PMTs for detection of numerous wavelengths, providing simultaneous multielement capability. The photodiode array (PDA) and more recently the charge transfer device (CTD) used with a conventional Czerny–Turner-type spectrometer can cover spectral windows of several tens of nanometers simultaneously. Spectrometers with
Paschen–Runge polychromators and with échelle gratings, equipped with solid-state detectors, have multielement capability and provide simultaneous UV and visible spectral coverage.

Most commercially available ICPMS instruments utilize radiofrequency quadrupole mass analyzers. Although quadrupole mass analyzers typically have a low resolution capability (ca. 0.5 u), their low cost, ease of coupling with an ICP source, and pseudosimultaneous mass detection make them attractive for elemental analysis with LA applications. The complete mass range from 1 to 250 u can be scanned in about 0.1 s.

Many LA applications require high-precision isotopic ratio measurements; high-resolution double-focusing ICPMS instruments equipped with multicollector array detectors are well suited for this purpose. ICPMS instruments with time-of-flight (TOF) analyzers were recently demonstrated with LA sampling. The TOF approach allows the collection of several thousand complete mass spectra per second. Owing to the transient nature of LA, ICPMS with a TOF analyzer is potentially advantageous for multielemental determinations, although to date only limited research has been conducted.

The detection capabilities of LA with ICPAES and ICPMS techniques depend significantly on the experimental conditions and equipment. ICPMS is typically used for minor and trace elemental analysis, whereas ICPAES has lower sensitivity and is primarily used for the analysis of major and minor constituents. Most geological applications, which require a high degree of spatial resolution for accurate microanalysis of inclusions and grains in minerals, utilize ICPMS instrumentation.

### 3.4 Detection Limits

One of the advantages of dry ICP conditions from LA sample introduction is that plasma excitation/ionization temperatures and electron number densities are typically higher than with a wet plasma produced during liquid nebulization. Dry plasma conditions enhance ionization and excitation processes. This benefit, along with simplified mass spectra (due to reduction of polyatomic interferences), provides improved detection characteristics. Absolute detection limits (absolute detectable amount of analyte mass) for rare-earth elements in silicate solutions; linear calibration curves can be generated for minor and trace elemental analysis.

Absolute detection limits (absolute detectable amount of analyte mass) for rare-earth elements in silicate solutions; linear calibration curves can be generated for minor and trace elemental analysis. Absolute detection limits (absolute detectable amount of analyte concentration in a sample) are compared; liquid nebulization sample introduction is better. This situation only exists because the amount of mass nebulized into the ICP is much greater than that ablated by the laser. Assuming a 2% efficiency for conventional pneumatic nebulizers with a 1 mL min\(^{-1}\) sampling rate, roughly 20 mg min\(^{-1}\) of solution is introduced into the ICP. In contrast, the amount of ablated mass per laser pulse is typically only 1 ng–1 μg. Hence for a laser repetition rate of 10 Hz and a particle transfer efficiency of 40% (maximum value reported in the literature), the amount of mass introduced into the ICP is only from 0.2 μg min\(^{-1}\) to 0.2 mg min\(^{-1}\). Hence the mass per unit time introduced into the ICP as a result of LA is about 10\(^2\)–10\(^3\) times less than that from liquid nebulization. Relative detection limits depend on the amount of mass and are therefore better for liquid nebulization sample introduction.

Typical detection limits, determined as three times the standard deviation of the blank, are in the low micrograms per gram and even nanograms per gram range for ICPMS detection with LA, in contrast to the picograms per gram level for liquid nebulization. For LA sampling with ICPAES, laser energies of 10–100 mJ are required, compared with only few milli- or even microjoules for sampling into the ICPMS. Typical LODs for LA sampling with ICPAES are in the micrograms per gram range and are comparable to those available from liquid nebulization sampling with ICPAES. Better detection limits can be achieved by increasing the amount of ablated mass per laser pulse, which can be realized by improvement in the laser energy coupling efficiency to the sample and/or improvement in entrainment/transport efficiency. When a sample was ablated inside the ICP torch, just below the discharge, particle losses associated with mass entrainment and transport were eliminated, and a significant improvement in detection characteristics was achieved.

### 3.5 Calibration and Optimization

The signal intensity recorded by ICPAES and ICPMS during sample introduction (both liquid nebulization and solid sampling) is proportional to the concentration of an element of interest in the sample. Absolute measurements require calibration procedures to be established, which remains an essential issue for chemical analysis. For liquid sample introduction, standards are relatively easy to obtain in the form of single- or multielemental solutions; linear calibration curves can be generated over three to six orders of magnitude for ICPAES and eight orders of magnitude for ICPMS. Assuming similar viscosities for the diluted sample and the standard solutions, the amount of aerosol aspirated into the ICP is determined by the nebulizer/spray chamber parameters. In contrast, during LA the amount of mass ablated and transported into the ICP may be different for samples and standards, if the standards are not matrix matched. For LA, an internal or external standardization procedure is required to compensate for changes in the quantity of mass ablated, even when the analyte concentration...
remains constant. Matrix-matched solid standards are generally required for instrument calibration.

3.5.1 Internal Standardization and Matrix Matching

The ablated mass is determined by the properties of the matrix, and close matching of calibration standards to samples is preferred. However, the chemical form in which the analyte is present in the sample was shown to influence the elemental response.\(^{(58)}\) Compensation for this effect often can be performed by normalization of analyte intensity to that of another element (internal standard). This procedure requires that the concentration of the internal standard, usually the matrix element, be either known [determined from independent methods, such as X-ray fluorescence (XRF) spectroscopy] or be constant in the sample and standards. In most cases, an internal standard provides excellent compensation for differences in ablation behavior for samples and standards. For trace elements in homogeneous samples, this approach has been used to improve the measurement precision to better than 1%.\(^{(18,49,59)}\) Internal standardization is especially useful for bulk analysis with samples and standards pressed into pellets,\(^{(90)}\) fused into glass beads,\(^{(49)}\) or preconcentrated in an NiS button\(^{(61)}\) where the internal standard is added during sample preparation. A single calibration graph was used for analysis of silicate rocks and limestones fused with Sc and Y oxides as internal standards.\(^{(62)}\) For cases in which relatively “good” standards were available, LA proved to be a reliable and accurate chemical analysis procedure. In some cases, however, internal standardization can be limited by differences in the ablation behavior of the sample and the standards, especially when standards are not matrix matched. For example, elemental fractionation of W relative to the internal standard Ca was shown to be different for a scheelite sample and a silicate glass calibration standard.\(^{(63)}\)

Calibration without an internal standard has been shown to be possible, especially in cases where only trace level impurities differ among the standards and sample; the trace impurities do not affect ablation behavior. Linear calibration curves were established and accurate trace elemental analysis was demonstrated for U,\(^{(64)}\) Au and Ag,\(^{(65)}\) and glass\(^{(66)}\) without internal standardization. In contrast, if the matrix properties change because of changes in the analyte concentration, the LA behavior is affected. For example, for the analysis of Zn in brasses, where Zn is a major element, linear calibration cannot be achieved, and other signal normalization procedures are needed for accurate calibration.\(^{(67)}\)

When internal standardization procedures are used for analyte characterization in an unknown sample, Equation (2) is applied:

\[
C_{sa}^M = C_{sa}^{IS} \times I_{sa}^M \times \frac{C_{st}^M}{C_{st}^{IS}} \times \frac{I_{st}^{IS}}{I_{st}^M} \tag{2}
\]

where \(C\) is the concentration and \(I\) is the ICP signal intensity. Subscripts \(sa\) and \(st\) denote sample and standard and superscripts \(M\) and \(IS\) correspond to the unknown analyte and the internal standard, respectively. This relationship assumes that the concentration of the internal standard is known and that fractionation between the analyte and internal standard is not significant, or is the same for analyte and standards.

3.5.2 Calibration with Liquid Standards

For many samples, matrix-matched standards will not be available. In these cases, external calibration can be performed using nebulization of liquid standards; a dual sample introduction method can be used to establish instrumental calibration with a series of standard solutions. To analyze the unknown sample by LA using liquid standards, wet ICP plasma conditions must be maintained.\(^{(68)}\) However, the use of liquids for calibration defeats two important advantages of LA and dry ICP: elimination of isobaric interferences in ICPMS and the generation of solvent waste.\(^{(12)}\) In addition, optimum ICP conditions will not be the same for LA and solution nebulization. For nebulization, the analyte dries from liquid droplets to form small particles in the plasma. For LA sampling, larger dry particles are introduced directly into the ICP.\(^{(45,48)}\) Atomization and excitation processes in the ICP are expected to be different for these two cases. Even if the water content is the same in the ICP, it is still possible that the excitation characteristics will be different because of the different vaporization mechanisms for nebulized solution and laser-ablated particles. On the other hand, calibration with dried solution aerosol\(^{(69)}\) or by direct LA of liquids\(^{(70,71)}\) does not significantly perturb dry ICP conditions.

LA of liquids has been shown to be effective for the analysis of microscopic fluid inclusions in minerals. In this method, direct ablation of a standard solution was used for external ICPMS calibration with Na as an internal standard.\(^{(71)}\) In another study, instrument calibration was done by using artificial fluid inclusions prepared by drawing a standard solution into a microcapillary tube\(^{(72)}\) or with microwells containing aqueous solutions.\(^{(73)}\)

3.5.3 External Standardization

For some samples, internal standardization may not be a viable option. In such cases, external standardization must be used to compensate for differences in ablation of the sample versus the standards. Several external
procedures have been demonstrated to compensate for changes in the quantity of ablated mass. They include light scattering,\textsuperscript{86,74,75} acoustic emission in the sample,\textsuperscript{19,76,77} or in the ambient medium\textsuperscript{76,78} the use of a mass monitor to collect a portion of the laser-ablated aerosol\textsuperscript{79} and the measurement of spectral emission intensity in the ICP and laser-induced plasma simultaneously.\textsuperscript{54,77} An absolute method to quantify the amount of mass ablated is to weight the sample before and after ablation.\textsuperscript{80} However, such direct mass measurements are tedious and may not be accurate because of the small quantity (\(< 1 \mu\text{g}\)) of mass ablated for each laser pulse, and because transport efficiency is not included.\textsuperscript{22,45} Determination of mass ablation and transport efficiencies is possible by collecting particles on a nonporous filter, which is an indication of the total mass transported to the ICP.

4 APPLICATIONS

Because of the unique properties of the laser, many novel applications for chemical analysis using the ICP have been demonstrated. This section presents a brief overview of applications that would be difficult or impossible to perform without the use of LA. Most of the applications utilize ICPMS because of its enhanced sensitivity.

4.1 Environmental and Oceanography

4.1.1 Tree Rings

Spatial patterns in the chemical content of tree rings can be used as a monitor for changes in atmospheric conditions, changes in soil chemistry, and the pollution history of an area. Laser ablation inductively coupled plasma mass spectrometry (LA/ICPMS) is an excellent approach to determine chemical content in tree samples because of the high spatial resolution provided by the focused laser beam, and the excellent sensitivity of ICPMS to measure very low detection levels for many elements.\textsuperscript{81–84} Watmough et al.\textsuperscript{83} obtained the quantitative multielement analysis of 11 elements in red maple tree rings; significant changes in these elements were measured for trees grown in contaminated soils adjacent to a metal smelter versus trees grown in unpolluted soils. GarbeSchongberg et al.\textsuperscript{84} analyzed pine and birch tree rings from Norway and Russia and discussed the elemental relationship with the pollution history of these areas.

4.1.2 Sea Shells

Trace-element fluctuations in sea shells represent environmental changes and major pollution events. In the work of Raith et al.,\textsuperscript{85} the inner to the outer walls of a shell were analyzed; the elemental changes between growth bands of the shell showed a history of heavy-metal pollution over the years. Vander Putten et al.\textsuperscript{86} measured spatial variations of Mg, Mn, Sr, Ba, and Pb in the calcite layer of \textit{Mytilus edulis} sea shells.

4.1.3 Airborne Particulates

The analysis of trace elements in airborne particulates provides unique signature information for monitoring air quality and air pollution. For example, arsenic, considered the major “marker element” of air pollution, is one of the most hazardous anthropogenic air pollutants affecting humans globally. Traditionally, membrane filters with small pore size have been used for collecting particulate samples. The entire filter is then digested and the total volume analyzed. LA is a perfect alternative for such analyses; the particulates can be ablated directly from the filter media. Tanaka et al.\textsuperscript{87} and Wang et al.\textsuperscript{88–90} analyzed airborne particulates for more than 20 major, minor, and trace elements using this approach.

4.1.4 High-resolution Analysis of Coral

The concentration of trace elements in coral skeletons can provide information about changes in seawater properties; calcification in reef-building corals is strongly affected by environmental factors such as temperature, light, water motion, and pollution.\textsuperscript{91} As coral grows, it secretes a calcareous skeleton into which trace elements are partitioned from the ambient seawater. Spatial analysis of the coral skeleton allows a detailed investigation of seasonal composition changes.\textsuperscript{92,93} Compared with the traditional method of sample milling, with processing and analysis by solution nebulization, LA/ICPMS provides in situ analysis of corals with spatial resolution less than 20 \(\mu\text{m}\). Sinclair et al.\textsuperscript{92} analyzed corals collected from Australia and showed that the elements B, Mg, Sr, and U exhibited seasonal variations, as shown in Figure 7. These fluctuations coincided with the changes of sea-surface temperature.

4.2 Geochemistry and Cosmochemistry

4.2.1 Uranium–Lead Geochronology

Zircon U–Pb geochronology is one of the principal dating tools used in the earth sciences; ages are calculated by measuring \(^{206}\text{Pb}/^{238}\text{U},^{207}\text{Pb}/^{235}\text{U}\), and \(^{207}\text{Pb}/^{206}\text{Pb}\) ratios. The conventional method for U–Pb isotopic analysis has been by thermal ionization mass spectrometry (TIMS) with chemical separation. However, very low blank values are required and the data represent the “average” of the bulk grains. LA/ICPMS has the ability to perform spatially resolved in situ analysis of U–Pb
isotopic compositions in zircons and similar minerals. Several groups\(^{94-97}\) have studied zircon and monazite samples using LA/ICPMS. Most of these studies only show \(^{207}\text{Pb}/^{206}\text{Pb}\) data and a few include the \(^{206}\text{Pb}/^{238}\text{U}\) ratio, because of a fractionation problem. Without the \(^{206}\text{Pb}/^{238}\text{U}\) ratio, the analysis cannot be extended to “young” (<600 Ma) zircon dating. In order to minimize Pb–U fractionation, methods such as active focusing, line scanning, and soft ablation (increasing the laser power when ablation is progressing) were attempted. Solving Pb–U fractionation is necessary to the success of LA/ICPMS for this application.

### 4.2.2 Inclusion Analysis

Microscopic inclusions in minerals contain direct evidence of the composition of fluids associated with large-scale material transport in the Earth’s interior. Quantitative knowledge of the elements and isotopic composition of these fluid inclusions is a prerequisite for understanding and modeling fluid–rock interactions. Detailed chemical information is difficult to obtain because of the very small size of these inclusions (typically \(10^{-11}-10^{-9}\) g).\(^{70}\) Crush–leach analysis or bulk analysis of quartz containing fluid inclusions can provide concentration ratios averaged over many inclusions, but most samples contain multiple generations of fluid inclusions of different compositions. LA/ICPMS for the analysis of individual microscopic inclusion has, therefore, received considerable attention. Good quantitative results have been published mainly for synthetic fluid inclusions,\(^{73,98}\) where a heavy trace element of a known concentration (e.g. Sr, U) was added as an internal standard. Günther et al.\(^{70}\) reported a method for measuring complex polyphase inclusions.

---

**Figure 7** Trace element and sea surface temperature (SST) profiles for coral from Australia’s Great Barrier Reef. Colored lines represent an average of three trace element profiles taken over the same coral track. Black lines are the instrumental SST data taken from the weather station. B, Mg, Sr, and U all display clear seasonal variation. Ba does not show a seasonality but displays a marked enrichment in the tissue zone. (Figure reproduced from original data with permission by Dr Daniel J. Sinclair\(^{92}\).)
using a stepwise opening procedure. A series of inclusions representing the fluid before, during, and after the deposition of cassiterite (SnO₂) in a tin deposit in Australia were analyzed by this method; physical and chemical mechanisms of ore precipitation were proposed based on these data.\(^{[99]}\)

### 4.2.3 Precise In Situ Analysis of Hafnium, Tungsten, Strontium, Lead, and Osmium Isotopes

Many elements are of significant interest for isotope geochemistry and need to be measured at trace levels with excellent precision. Multiple collector inductively coupled plasma mass spectrometry (MC/ICPMS) with a magnetic sector is a new technology for the measurement of isotopic compositions with very high precision. It is particularly suited for elements with high first ionization potentials such as Hf, W, and Os, which cannot be measured with good precision using conventional TIMS. Combined with LA sampling, in situ isotopic measurements at the microscopic scale are possible. Although this technology is still in its infancy, diverse applications have already led to a number of important scientific developments.\(^{[100]}\)

The initial Hf isotopic composition is more reliable than initial Nd as a geochemical tracer owing to the immobility of Hf. The Hf isotopic composition in zircon samples was analyzed by Thirlwall and Walder.\(^{[101]}\)

In low-temperature geochemistry, Hf isotopes may provide the most reliable and sensitive isotopic proxy for hydrothermal activity in the ocean. The Hf isotopic compositions in iron–manganese nodules and crusts were studied by Godfrey et al.\(^{[102]}\) and the data reflected the concomitant growth from seawater and pore fluids. There is strong interest in measuring W and Hf isotopic compositions with high precision using LA with MC/ICPMS. The \(^{182}\)Hf–\(^{182}\)W system is a method for constraining timescales of accretion and metal–silicate differentiation in planets; the age of the Earth’s core, the Moon, and Mars have been measured using this new chronometer.\(^{[100]}\)

Sr and Pb isotopic compositions are significant for geochemistry and oceanography research. Analysis of these elements traditionally requires complicated chemical separation procedures. LA with MC/ICPMS provided accurate and precise measurement of \(^{87}\)Sr/\(^{86}\)Sr isotopic ratios in geological materials.\(^{[103]}\) Pb isotopic compositions in a ferromanganese crust from the Pacific ocean were analyzed by Christensen et al.\(^{[104]}\) and the authors concluded that the Pb isotopic data could be used to probe climate-driven changes in ocean circulation. Analysis of Os isotopic ratios for iridosmine samples was reported using LA with MC/ICPMS.\(^{[105]}\) The mineral iridosmine has been used for the definition of the Os isotopic evolution of the mantle.

### 4.2.4 Bulk and Microbeam Analysis of Rocks and Minerals

Bulk and spatial analyses of rocks and minerals for elemental and isotopic compositions can provide fundamental information to help solve diverse geological and environmental problems. The application of LA/ICPMS for the analysis of whole-rock geological samples, such as pressed power pellets and lithium metaborate fusions, has been described by several authors.\(^{[106,107]}\) In most of these studies, the measurement of rare-earth elements (Zr, Hf, U, Th, Sr Rb, Ba, Nb, Ta) was emphasized. LA/ICPMS was also used to determine the platinum group elements (Ru, Rh, Pd, Os, Ir and Pt) and gold, which have very low natural abundance but great economic and geological importance.\(^{[108]}\)

The spatially resolved analysis of elements within minerals provides crystal-growth information and the variation in the physical and chemical nature of environments in which they grew. LA/ICPMS analysis, either on a single mineral grain or on a thin section, can provide such information. LA/ICPMS analyses of minerals such as calcite, zircon, olivine, plagioclase, feldspar, titannite, apatite, clinopyroxene, amphibole, and garnet have been reported.\(^{[109–111]}\)

### 4.3 Forensics and Authentication

#### 4.3.1 Authentication of Antique Objects

Chemical analysis is an excellent approach for verifying the authenticity of valuable artifacts. Obviously, the analytical method for authenticity verification of precious antiques should be either nondestructive or require extremely small sample quantities. Using LA/ICPMS, visible damage can be restricted to an acceptable minimum. Such studies were reported by Devos et al.,\(^{[112]}\) in which a specially designed sample chamber was used, and almost invisible 100-\(\mu\)m craters were produced on antique silver objects. The elements Zn, Cd, Sn, Sb, Au, Pb, and Bi were measured, and their contents were used to distinguish forgery in silver antiques. Similar studies were reported by Wanner et al.,\(^{[113]}\) for trace element analyses of archaeological samples such as ancient coins, various antique silver items, and ancient iron. Owing to surface roughness of the samples, an autofocus system was used to achieve reproducible ablation conditions. In these experiments, a lateral resolution of 50\(\mu\)m and absolute detection limits of 1–1.4 pg were achieved.

#### 4.3.2 Fingerprinting Crime Scene Evidence

Many criminal activities result in the generation of debris or other materials, which become available to investigating authorities as physical evidence of the crime. However, the generation of traditional analytical and
forensic chemical data is often costly and time-consuming. LA/ICPMS offers the potential for producing fast, definitive, and cost-effective forensic chemical analysis for use in identifying physical evidence that relates to the scene of a crime. Watling et al.\textsuperscript{(114)} examined several kinds of glass and steel samples as physical evidence of a crime. They developed software to facilitate an intercomparison of three elements simultaneously (ternary plots) for large groups of samples. This approach established both the reproducibility of the “fingerprint” and the uniqueness of interelement associations. A similar idea was used to source the provenance of cannabis. Certain elements from a specific area or geological environment characterize uniquely the source of the plant. Watling\textsuperscript{(115)} showed the trace element association “fingerprint” patterns of cannabis crops and the potential tracing of these crops to specific geological environments. The association of elements formed the basis for determining the provenance of cannabis crops and samples recovered during police drug raids.

4.4 Waste-sample Analysis

LA has many advantages when used to analyze radiological contaminated samples. For example, organic solvents or concentrated acids that are required for classical separation procedures will not be needed for LA sampling. Also, with LA, much less total sample (<1 µg) will be required, greatly reducing the risks associated with sample handling and contamination, and personnel exposure. Finally, elemental and isotopic analysis can be obtained entirely within a hot cell environment, further reducing the risk of contamination.\textsuperscript{(116)} High-level waste analysis using LA/ICPMS was detailed by Smith et al.\textsuperscript{(117)} A unique LA facility has been established in a hot cell environment at the Hanford Site for direct characterization of tank waste samples. Applications of LA and high-resolution ICPAES in the nuclear industry, especially high-resolution isotopic analysis of U and determination of lanthanides, were reported by Giglio et al.\textsuperscript{(116)} and Zamzow et al.\textsuperscript{(118)}

5 NONINDUCTIVELY COUPLED PLASMA APPLICATIONS

There are many LA applications that do not rely on particle digestion by an analytical source (ICP, flame, etc.), but instead directly measure the ablated atomic mass. Laser-induced breakdown spectroscopy (LIBS), described in more detail in the article Laser-induced Breakdown Spectroscopy, involves monitoring spectroscopic emission intensity directly in the laser plume. Other applications involve direct MS detection of the ablated mass, with and without secondary ionization, e.g. resonance ionization mass spectrometry (RIMS) and matrix-assisted laser desorption/ionization (MALDI). It would be impossible to discuss these numerous applications without doubling the length of this article. Instead, one particular technique employed by our research group is presented.

5.1 Laser Ablation Ion-storage Time-of-flight Mass Spectrometry

A new technique for single particle analysis was developed that uses ion-trap and TOF mass spectrometers. Commercial LA systems with imaging capabilities involve a chamber in which the ablated mass is entrained into a gas stream and transported to the analytical source by several meters of tubing, thereby diluting the mass vapor and influencing detection sensitivity. For single-particle analysis, excellent sensitivity must be available because of the limited absolute mass from a micrometer-sized particle. To overcome the dilution and sensitivity limitations, an instrument was developed using LA inside an ion-storage time-of-flight mass spectrometry (IS/TOFMS) system with an imaging camera to observe, select, vaporize, ionize, and analyze individual particles or spatial locations on a solid surface.

An ion trap was designed such that a pulsed Nd: YAG laser beam could ablate a sample affixed to a probe inserted radially through the ring electrode (Figure 8). Once the particle is selected using the imaging system, it is directly ablated/ionized by the laser beam. A primary advantage of this system is that the ions are generated directly inside the ion trap. The ion trap is not used as the mass spectrometer, because space-charge effects would critically influence the mass resolution. Instead, the ion trap is used only as a storage device and the TOF performs the MS. In this way, space charging is significantly reduced except in cases when using extremely high laser fluence, which is not necessary for excellent sensitivity. In preliminary experiments, trace contaminants of Ag, Sn, and Sb were measured in a Pb target with a single laser shot. Reproducible spectra could be measured with only approximately 10 µJ of laser energy. The laser-beam focusing system provided a spatial resolution of approximately 12 µm, with imaging capability to guide the laser beam to a specific location on the sample. The photographs in Figure 9(a) and (b) shows images of the laser-induced craters in hair and alloy samples, respectively.

6 PERSPECTIVES AND FUTURE TRENDS

LA and atomic spectroscopy have become a mature partnership providing significant benefits to both techniques. On the one hand, LA provides the best method
Figure 8 Schematic diagram of ion-trap TOF mass spectrometer with imaging capabilities. The system was designed such that a pulsed Nd: YAG laser beam could ablate a selected sample inside the ion trap mass spectrometer.

Figure 9 Images of the laser-induced craters in (a) hair and (b) alloy samples.

for directly converting a solid-phase sample into gas-phase constituents. On the other hand, atomic spectroscopy brings to the relationship a powerful method for understanding the fundamental mechanisms of ablation processes. For atomic spectroscopy, the relationship is continuing to flourish, as can be seen by the increasing number of applications, number of published papers and conference symposia, and new commercial systems. This article has primarily addressed LA as a sampling technique for atomic spectroscopy. There are numerous papers in the literature in which atomic spectroscopy is used to study the fundamental behavior of ablation processes; an example is the work by Bushaw and Alexander using high-resolution time-resolved atomic absorption spectroscopy for the investigation of LA plume dynamics. A literature search using the two keywords “laser” and “ablation” provided approximately 2500 published papers in the Current Contents database, increasing continuously from 1990 to the present. Interest in LA continues to flourish because of applications in atomic spectroscopy, and also medical, semiconductor, materials, and other areas. When matrix-matched standards are available, LA is an ideal quantitative method with excellent accuracy and precision. In cases when matrix-matched standards are not available, LA with atomic spectroscopy is suitable for semiquantitative analysis. Further development of LA and its maturation into an accurate and precise sampling technique for atomic spectroscopy will occur through understanding of fundamental processes and the means to control them. The benefits of LA sampling and atomic spectroscopy warrant success.

LASER ABLATION IN ATOMIC SPECTROSCOPY

56. X.R. Liu, G. Horlick, ‘In Situ Laser Ablation Sampling for Inductively Coupled Plasma Atomic Emission

LASER ABLATION IN ATOMIC SPECTROSCOPY

Laser light has a number of spectacular properties that make it useful for analytical spectrometry. One is that it has a high directionality (i.e. it looks like a real “beam”). This implies, among other things, that it can be focused down to micrometer-sized spots. Another is that pulsed lasers can emit large amounts of light in very short pulses (often with a duration of $10^{-9} - 10^{-8}$ s). These two properties imply that laser light often can reach high irradiance ($W m^{-2}$), which is of importance for a number of applications, not least when laser light is used for vaporization and/or atomization purposes of solid material. The most important attribute for spectroscopic applications, however, is that it often has a narrow frequency width (in the MHz–GHz range). This implies that laser light can induce one specific transition in one particular species at a time. The narrow frequency width is thus the basis for the high species selectivity that laser spectroscopic techniques possess. In addition, the combination of high irradiance and a narrow frequency width often gives laser light such staggering spectral irradiance ($W m^{-2} Hz^{-1}$) that a significant fraction of the atoms under illumination can produce at least one detectable event during the interaction time (one or several
photon or an ion–electron pair). This explains why laser spectroscopic techniques can benefit from high species sensitivity.

The main purpose of this review article is to describe the theory and instrumentation for the field of laser spectroscopic techniques for analytical atomic spectrometry. This implies that techniques that use laser light for nonspectroscopic purposes, such as vaporization, and/or atomization purposes, e.g. laser ablation, laser-induced plasma spectrometry, laser mass spectrometry and laser-induced breakdown spectrosocpy, will not be covered here. In addition, because atomic spectra in general consist of a few strong and narrow-band transitions (whose widths often are comparable to those of the light from tunable laser systems and therefore seldom overlap with those from other atomic species) whereas those of molecules comprise a few broader, weaker and to a certain extent structured transition bands (which thus overlap more often with those of other molecular species), laser spectrometric techniques often show the highest sensitivity and selectivity when atomic species are detected. This is the main reason why this review focuses upon the use of laser spectrometric techniques for analytical atomic spectrometry. This implies, in turn, that laser-based spectrometric techniques that predominantly detect molecules, e.g. Raman, thermal lensing and photoacoustic spectrometry, and spectrofluorometry, will not be discussed.

This theory and instrumentation review focuses upon the most useful and versatile laser spectroscopic techniques for analytical atomic spectrometry. These techniques are based upon the concepts of fluorescence, ionization or absorption. Those based upon fluorescence are often referred to as either laser-induced fluorescence (LIF) or laser-excited atomic fluorescence spectrometry (LEAFS), whereas those based upon ionization are termed either laser-enhanced ionization (LEI) or resonance ionization spectrometry (RIS). The working principles, instrumentation and present status of laser-induced fluorescence/laser-excited atomic fluorescence spectrometry (LIF/LEAFS) and LEI are covered in some detail in two separate sections, whereas RIS is covered more briefly. The reason for this is the broader versatility and applicability of LEI: it can be performed in a variety of atomizers, including those working under atmospheric pressure, whereas RIS has to be carried out in a vacuum and thus with significantly more complex instrumentation. However, because the laser instrumentation and the theoretical basis for all these techniques are quite similar, a short introduction to laser instrumentation and a theory section that outlines the common basic features of excitation of atoms by laser light precede the detailed descriptions. Those laser spectroscopic techniques that are based upon absorption and used for analytical atomic spectrometry are, nowadays, all performed in conjunction with some sort of modulation methodology (often wavelength-modulation (WM)), frequently by the use of diode lasers owing to their rapid tunability. They are therefore often referred to as WM diode laser (atomic) absorption techniques and are covered in a separate section.

Typical analytical qualities, e.g. limits of detection (LOD) and selectivity, as well as the typical strengths and limitations of each of these techniques, are given or discussed. It is concluded among other things that the most impressive performance of the LIF/LEAFS technique has been obtained together with the graphite furnace (GF) as atomizer, resulting in detection limits in the femtogram range and a very high selectivity for a large variety of elements. LEI, which has found its best use with the flame as atomizer, can provide LOD in the pg/mL range for many elements. It does not, however, show the same high selectivity as the LIF/LEAFS technique because it suffers from background effects when samples with high concentrations of easily ionized elements (EIEs) are analyzed. RIS combines a high sensitivity with an extraordinary selectivity, but instead has to pay the price of a more complex instrumentation. It was demonstrated earlier, for example, that the RIS technique is able to provide single atom detection (SAD). Because RIS in general is performed in a vacuum it can also provide good isotopic selectivity. Although not yet applied to a broad range of elements for analytical applications, it has shown impressive LOD (in the attogram range) and excellent isotopic selectivity (>10⁹) under a few specific conditions. The wavelength modulation diode laser absorption spectrometry (WM-DLAS) technique shows good promise for becoming a user-friendly and widespread detection technique because it requires less complex instrumentation than most other laser spectroscopic techniques. Used with the GF as atomizer, LOD in the femtogram range have been achieved. The WM-DLAS technique also has good ability to correct for various types of unstructured background absorption signals that might appear when samples with complex matrices are analyzed. One drawback, however, is that its applicability is still restricted owing to the limited availability of diode lasers that emit light in the visible and ultraviolet (UV) region. The WM-DLAS technique, therefore, has been applied to only a limited number of elements so far. A common denominator for all these laser spectroscopic techniques is that they often have a large linear dynamic range (LDR). The LIF/LEAFS technique, for example, has demonstrated an LDR of 5–7 orders of magnitude. Finally, in addition to being used as sensitive and selective tools for analytical assessments, the laser spectroscopic techniques often show an excellent applicability to diagnostic studies (e.g. for the determination of processes such as atomization, diffusion, collision or ionization).
1 INTRODUCTION

Analytical spectrometry refers to a family of techniques by which a sample is characterized with regard to its content of atoms (or molecules) by spectroscopic means. It is customary to distinguish between optical (e.g. laser) and mass spectrometric techniques. The underlying foundation of optical spectrometric techniques is the quantization of energy levels, which gives each type of atomic or molecular species its own unique set of transition wavelengths, whereas mass spectrometric techniques rely on the fact that each type of species has a unique mass. The present review is solely concerned with the use of optical spectrometric techniques. The reader is referred to other articles in this encyclopedia for a description of mass spectrometric techniques (Mass Spectrometry: Overview and History; Time-of-flight Mass Spectrometry; Secondary Ion Mass Spectrometry as Related to Surface Analysis; Tandem Mass Spectrometry: Fundamentals and Instrumentation; Quadrupole Ion Trap Mass Spectrometer; Literature of Mass Spectrometry).

1.1 Conventional Techniques for Analytical Atomic Spectrometry – Emission and Absorption

The two most commonly used conventional (optical) spectrometric techniques for analytical atomic spectrometry are emission and absorption spectroscopy. In both of these techniques, the sample to be analyzed is introduced into a hot environment in which it is vaporized and subsequently atomized. Emission spectroscopy relies upon the fact that the heat of the atomizer thermally excites free atoms, which subsequently decay to lower-lying states by spontaneous emission. The wavelength distribution and the intensity of the spontaneously emitted light are measures of the analytical content of the sample. In absorption spectroscopy, the wavelength distribution and the amount of the light absorbed when it is passing the atomized sample are measures of the analytical content of the sample.

Although both of these techniques have been developed to a considerable level of sophistication and applicability throughout the years (with a variety of atomizers), they suffer from a few inevitable inherent limitations. Emission spectrometry has a limited sensitivity (the thermal population of the excited states is usually rather low) and selectivity (given solely by the dispersive power of the detection instrumentation). In addition, the precision and accuracy are limited (the amount of light emitted for a given amount of analyte varies strongly with temperature, so any minor fluctuation of the atomizer conditions, e.g. from the matrix composition of the sample, can affect the sensitivity). The absorption technique is limited by influences from unspecific background absorption and stray light (although a variety of detection procedures, e.g. the D_2 lamp and Zeeman background correction, have been developed throughout the years in order to overcome these limitations). The present status of the emission and absorption spectrometry techniques can be found elsewhere in the literature or in this encyclopedia (Atomic Spectroscopy: Introduction; Inductively Coupled Plasma/Optical Emission Spectrometry; Flame and Vapor Generation Atomic Absorption Spectrometry; Graphite Furnace Atomic Absorption Spectrometry; Background Correction Methods in Atomic Absorption Spectroscopy; Flame and Graphite Furnace Atomic Absorption Spectrometry in Environmental Analysis).

1.2 Lasers as Powerful Light Sources for Analytical Atomic Spectrometry

With the advent of the first laser (an acronym for light by amplified spontaneous emission (ASE) of Radiation) in 1960, many of the limitations of the conventional analytical spectrometry techniques were expected to be overcome. Laser light has a number of spectacular properties that make it exceptionally useful for analytical spectrometry, the most important of which are: high directionality (i.e. it looks like a real “beam” of light), which implies that it has a high irradiance (W m^-2); and an extremely narrow frequency width (i.e. it can often be considered to consist of only “one” wavelength), implying that it has an even more impressive spectral irradiance (W m^-2 Hz^-1). In addition, pulsed lasers can produce very short laser pulses, thus temporarily producing very high peak powers and thereby sometimes even staggering spectral irradiances (which is often of importance for analytical applications).

These properties give the laser-based spectrometric techniques both high sensitivity and excellent selectivity. The high sensitivity, which predominantly stems from the high irradiance of the laser light, implies that a significant fraction of the atoms under illumination can produce a detectable event (e.g. a high production of photons/ions/electrons per illuminated atom). Laser-based techniques, for example, can be used successfully for SAD. The high selectivity, which mainly originates from the narrow bandwidth of the light, comes from the fact that it is often possible to induce one (and often only one) specific transition in one particular type of species at a time.

Several types of lasers with a variety of qualities have been developed since the first laser saw the light of day. The fact that some types of lasers can be scanned (or tuned) over the absorption profile (referred to as tunable lasers) makes them useful for analytical spectrometry (as well as indispensable for atomic physics). With access to the tunable high-irradiance light sources
that lasers constitute, a whole new family of detection techniques for analytical spectrometry has emerged during the last decades.\(^{15–21}\)

### 1.3 Use of Lasers for Analytical Spectrometry

Laser light can be used in a variety of ways for analytical spectrometric purposes. It is customary to distinguish between spectrometric and nonspectrometric applications.

#### 1.3.1 Lasers for Spectrometric Applications – Detection of Atoms versus Molecules

Laser-based spectrometric techniques refer to those techniques in which the narrow bandwidth of the laser light is used to provide a species-selective interaction with the sample. Although laser spectrometric techniques can be used successfully for the detection of both atoms and molecules, they show the highest sensitivity and selectivity when atomic species are detected because atomic spectra generally consist of a few strong and narrow-band transitions (whose widths often are comparable to those of the light from a tunable laser system) as opposed to those of molecules, which comprise a few broader, weaker and to a certain extent structured transition bands. This is the main reason why this review is devoted to the use of laser spectrometric techniques for analytical atomic spectrometry. This implies, in turn, that laser-based spectrometric techniques that predominantly detect molecules, e.g. Raman,\(^{22}\) thermal lensing and photoacoustic spectrometry,\(^{23–28}\) spectrofluorometry,\(^{29–31}\) optoacoustic detection\(^{32}\) and degenerate four-wave mixing,\(^{33}\) will not be covered in this review. The reader is referred to other articles in this encyclopedia for further information about these types of technique (Raman Spectroscopy: Introduction; Raman Scattering, Fundamentals; Dispersive Raman Spectroscopy, Current Instrumental Designs; Fourier Transform Raman Instrumentation; Raman Microscopy and Imaging).

#### 1.3.2 Lasers for Nonspectrometric Analytical Applications

Lasers can also be used as a tool for vaporization and/or atomization of the sample in conjunction with various types of conventional detection techniques. There are a number of closely related techniques in this field: e.g. laser ablation, laser-induced plasma spectrometry, laser mass spectrometry and laser-induced breakdown spectroscopy. However, because this use of lasers does not contribute to the elemental selectivity through their narrow bandwidth, none of these types of technique will be covered in this review. The reader is again referred to other articles in this encyclopedia (e.g. Laser-induced Breakdown Spectroscopy) or to the literature for this type of application of lasers in analytical spectrometry.\(^{34}\)

### 1.4 Laser Spectrometric Techniques for Analytical Atomic Spectrometry – Fluorescence, Ionization and Absorption

Although a number of different laser-based spectroscopic techniques have been scrutinized for their analytical applicability throughout the years, the techniques based upon fluorescence, ionization and absorption have been shown to be the most useful and versatile for analytical atomic spectrometry.

#### 1.4.1 Laser-induced Fluorescence Spectrometry

Tuned to a particular transition in one specific element, the narrow-band laser light will selectively increase the number of excited analyte species far above the thermal levels. This implies that the emission will be increased considerably. Such laser-enhanced emission is generally termed LIF. By detecting this fluorescent light by suitable means (most often a spectrometer and a light-sensitive detector), an assessment of the amount (or concentration) of the analyte can be made.\(^{35}\) LIF is a very useful and versatile technique that has found applications in a number of areas (e.g. atomic physics, quantum optics, environmental monitoring, combustion analysis and analytical spectrometry\(^{36}\)). When applied to analytical spectrometry for the detection of atoms or molecules, it appears frequently under the name LEAFS\(^{37,38}\) or laser-excited molecular fluorescence spectrometry (LEMOFS).\(^{38}\)

#### 1.4.2 Laser Ionization Spectrometry

Laser-excited atoms cannot only decay to lower-lying states by emission of photons (i.e. fluorescence) or by collisions with surrounding species (i.e. by inelastic or so-called quenching collisions), but they can also be ionized as a direct (or indirect) consequence of the laser illumination. Techniques that are based on a monitoring of the production of charged species (i.e. ions or electrons) that result because of laser illumination are therefore termed laser ionization spectrometry techniques. A laser ionization technique can thus be seen as an optical-to-electrical transducer whose output (number of charges produced) depends on the amount (or concentration) of the analyte to be assessed. In analytical applications, the ionization techniques are most often referred to as either LEI spectrometry\(^{39,40}\) or RIS.\(^{11,19,41}\) The main difference between these two types of technique is that RIS is performed under a vacuum but LEI needs to be
performed in an environment in which there is already an omnipresent thermal ionization. The reason for this is that the laser light is used for excitation as well as for ionization of the analytes in RIS, whereas the atoms only need to be promoted to an excited state by the laser light in the LEI technique (because the ionization is provided by an existing thermal ionization process in the atomic reservoir in this technique; see further discussion below). LEI has therefore the advantage over RIS that it can be performed in a variety of atomizers suitable for analytical purposes (flames, furnaces, etc.).

1.4.3 Laser Absorption Spectrometry

Tuned to a particular transition in an element, the laser light will not only increase the number of excited species in the sample but it will also experience an attenuation (one photon will be absorbed for each excitation event). This implies that the light will be attenuated as it passes a cloud of absorbing species. This is the basis for absorption techniques.

Laser-based absorption techniques have found best use for analytical spectrometry in combination with various modulation methodologies. Correctly used, the modulation reduces the noise in the system. Hence, although fluorescence and ionization techniques benefit from a high production of photons or ions/electrons, the laser-based absorption techniques benefit from a reduction of the noise in the system that the modulation brings. In addition, because diode lasers have the unique property that they can be tuned (i.e. modulated) at significantly higher rates than other tunable lasers, modulation absorption techniques often incorporate diode lasers and are therefore often referred to as wavelength-modulation (WM) or frequency-modulation (FM) diode laser absorption techniques.\(^{42,43}\)

1.4.4 Coverage of this Review

Because these three laser spectroscopic techniques (fluorescence, ionization and absorption spectrometry) combine high sensitivity, high selectivity and broad versatility for the detection of a large variety of elements in trace concentrations/amounts in various types of samples, this review will focus upon their foundations, theory and instrumentation.

1.5 Organization of this Review

Section 2 gives some typical properties of modern laser systems suitable for analytical spectrometry. Section 3 covers the most important basic theoretical concepts related to the excitation of atoms by laser light and gives an introduction to the nomenclature and terminology of the field. Section 4 reviews the LIF/LEAFS technique in analytical applications. Section 5 deals with ionization techniques. After a short comparison of the RIS and the LEI techniques, most of the section is concerned with LEI owing to its broader versatility, whereas RIS is described more briefly at the end. Section 6 first makes some comments about FM and WM techniques in general, before it focuses the presentation on the WM diode laser absorption technique due to its suitability for analytical spectrometry. Finally, section 7 makes some concluding remarks about the field of laser spectrometric techniques for analytical atomic spectrometry and speculates briefly about its future.

2 LASER INSTRUMENTATION

Virtually all lasers used for analytical spectrometry are tunable (i.e. their wavelength can be tuned continuously over at least a certain part of the spectrum). With the exception of diode laser systems, a tunable laser system consists of a pump laser (producing nontunable high-power light) and a tunable laser (converting the pump laser light to preferably narrow-band tunable laser light).

Most tunable laser systems can be classified as either continuous-wave or pulsed systems, dictated by the qualities of the pump laser. Tunable continuous-wave laser systems most often consist of ion-laser-pumped dye laser or Ti:sapphire laser systems, or the diode lasers that have gained increasing interest during latter years. Tunable pulsed laser systems, which have dominated the area of laser analytical spectrometry for a number of years, consist most often now of excimer- or neodymium:yttrium aluminum garnet (Nd:YAG)-pumped dye laser or optical parametric oscillator (OPO) systems (although nitrogen- or flashlamp-pumped dye laser systems were common during the first years). Atomic-vapor-based systems, which have been used only occasionally for analytical spectrometry, take an intermediate position with pulse frequencies significantly exceeding and pulse energies significantly falling short of those of ordinary pulsed laser systems. A thorough and well-updated overview of the properties of laser systems in terms of the requirements of the field of analytical spectrometry has been given recently by Sneddon et al.\(^{44}\)

2.1 Tunable Continuous-wave Laser Systems

2.1.1 Continuous-wave Dye Laser or Ti:sapphire Laser Systems

Typical continuous-wave pump lasers produce light of a few (or tens of) watts. A tunable continuous-wave dye laser or Ti:sapphire laser system can therefore typically produce narrow-band laser light in the milliwatt to watt
range in the visible part of the spectrum. Light in the UV region, which often is needed for excitation of atomic species, can be produced at microwatt powers by use of frequency-doubling instrumentation (frequency-doubling is done in nonlinear crystals in which two photons of the incoming light beam are being combined to one photon of twice the energy, i.e. half the incoming wavelength).

Although laser beams most often are produced and used with typical diameters of a few millimeters, they can be focused down to spots of micrometer-size dimensions. This implies that laser irradiances from tunable continuous-wave laser systems can, in theory, range from fractions of W m$^{-2}$ to $10^{12}$ W m$^{-2}$, with “typical” numbers in the $10^5$–$10^6$ W m$^{-2}$ range (for the case of 1–10 mW of light and a beam area of 10 mm$^2$).

In addition, monochromatic continuous-wave laser light can be produced with a variety of bandwidths, often in the megahertz range (from a few to some hundreds of megahertz, depending on the type of system, type of stabilization, etc.). This implies that tunable continuous-wave laser light can be produced with spectral irradiances up to $10^8$ W m$^{-2}$ Hz$^{-1}$ under strongly focused conditions, with “typical” values in the $10^{-6}$–$10^{-4}$ W m$^{-2}$ Hz$^{-1}$ range for unfocused situations.

Comparing these numbers with those of an ordinary light source, e.g. the light from the Sun on the surface of the Earth (around $10^3$ W m$^{-2}$), as is done in Table 1, one finds that the irradiances in fact are comparable. However, because sunlight is distributed over a large part of the spectrum (over approximately $10^{14}$ Hz), the typical spectral irradiance of tunable continuous-wave laser light ($10^{-6}$–$10^{-4}$ W m$^{-2}$ Hz$^{-1}$) is several orders of magnitude larger than that of the sunlight ($10^{-11}$ W m$^{-2}$ Hz$^{-1}$).

<table>
<thead>
<tr>
<th>Irradiance$^a$ (W m$^{-2}$)</th>

$^a$ The values for the laser systems are given for a “typical” experimental situation with a beam diameter of a few millimeters. Values in parentheses refer to strongly focused situations (with a spot size of micrometer size dimensions).

$^b$ At the surface of the Earth.

$^c$ Values are given for a “typical” argon ion laser-pumped dye laser system.

$^d$ Values are given for a “typical” Nd: YAG- or excimer-pumped dye laser system with nanosecond pulse duration but are also in reasonable agreement with those for OPO systems.

2.1.2 Diode Lasers

Modern diode lasers suitable for analytical spectrometry (i.e. single-mode lasers) can produce light at powers of tens of milliwatts directly (mostly in the red or infrared region). By using external frequency-doubling instrumentation, powers in the microwatt region (and occasionally in the milliwatt region) can be produced.

In addition to the aforementioned properties, diode lasers possess yet another unique property: namely, an extraordinary rapid and versatile tunability. Diode lasers are controlled by their temperature and injection current.$^{43}$ A modulation of the wavelength can be accomplished by a rapid modulation of the injection current. Although modern diode laser systems can be modulated at gigahertz frequencies for communication purposes, most diode laser systems for analytical purposes are modulated in the megahertz range (for FM techniques) and the kilohertz range (for WM techniques).$^{42,46}$

2.2 Tunable Pulsed Laser Systems

2.2.1 Pump Lasers

The comparison between laser light and conventional light becomes even more spectacular when pulsed lasers are considered. Nd: YAG lasers can in general produce light with higher pulse energies (about 1 J per pulse) than can excimer lasers (typically a few hundred millijoules per pulse). However, because the fundamental wavelength of Nd: YAG-produced light is 1064 nm, it has to be converted to more suitable wavelengths in order to make pumping of dye lasers or OPOs possible. Light at 532- and 355-nm wavelengths can be produced by frequency doubling of the 1064-nm light and frequency-mixing of the 532- and 1064-nm light, respectively, in nonlinear crystals. Crystals dedicated for frequency conversion of Nd: YAG laser light have rather high conversion efficiencies, implying that frequency-doubled and frequency-tripled light can be produced at pulse energies comparable to that of excimer laser systems (which produce light useful for dye laser pumping directly, most often at 308 nm when XeCl is used as the laser firing medium).

Typical pulse lengths for these types of laser are in the nanosecond range (typically 5 ns for Nd: YAG-pumped systems and often around 10–30 ns for excimer-pumped systems). The shorter pulse lengths of Nd: YAG lasers therefore give them an edge over excimer lasers when it comes to irradiances but also a handicap when it comes to the illumination time (as will be discussed in the following section). The excimer systems, however, have an irrefutable advantage when it comes to repetition rates. Although many Nd: YAG lasers can produce light only at a repetition rate of 10 or 30 Hz (and some at 50 Hz),
it is not uncommon for excimer lasers to run at several hundred hertz (some even up to 500 Hz).

2.2.2 Pulsed Dye Laser Systems

A pulsed dye laser system can produce tunable laser light in the low to medium millijoule range in the visible part of the spectrum. Because one particular dye can produce light only over a certain part of the spectrum (typically a few tens of nanometers), a number of different dyes are needed to cover the entire spectrum. Typical conversion efficiencies of pulsed dye lasers depend on the choice of dye and the position within the laser firing range of the dye. Peak conversion efficiencies of various dyes range normally from a few per cent to a few tens per cent, with the highest efficiencies for coumarins (in the 450–600 nm range) for excimer-pumped dye lasers and for rhodamines (in the 560–650 nm range) for Nd:YAG-pumped systems. The fundamental wavelength ranges covered by these systems (i.e., using no nonlinear frequency-doubling or frequency-mixing instrumentation after the dye laser) are roughly 330–980 nm for XeCl-based excimer laser systems and 400–900 nm for Nd:YAG-based systems.

In order to create tunable UV light, the dye laser light has to be frequency-doubled in a nonlinear crystal. The conversion efficiencies of such crystals range from a fraction of a per cent to some tens per cent. Hence, UV light can most often be produced by pulsed dye laser systems with pulse energies in the micro- to low-millijoule range. The total wavelength ranges of pulsed dye laser systems depend on the particular nonlinear frequency-doubling (or frequency-mixing) schemes used. In general, however, virtually the entire wavelength region from below 200 nm up to around 1 µm can nowadays be covered with pulsed dye laser systems.

The irradiance from excimer- or Nd:YAG-pumped dye laser systems can be as high as 10¹⁰ W m⁻² (assuming 25 mJ of light distributed over 5 ns and focused down to an area of 5 µm²), with “typical” values in the 10⁵–10¹⁰ W m⁻² range (for 10 µJ–1 mJ of light distributed over 10 ns and a beam area of 10 mm²). Unless any special precautions are taken, tunable light produced by pulsed dye laser systems has typical spectral bandwidths of a few gigahertz. This implies that the corresponding spectral irradiance can become as high as 10⁸ W m⁻² Hz⁻¹, but is under more normal conditions around 0.1–10 W m⁻² Hz⁻¹, i.e., several orders of magnitude larger than from tunable continuous-wave laser systems (see Table 1).

2.2.3 Pulsed Optical Parametric Oscillator Systems

Tunable OPO laser systems have been developed during the latter years as a viable alternative to dye lasers. This all-solid-state laser has considerably improved the creation of pulsed tunable laser light. An OPO needs to be pumped by a pump laser in a similar way to dye lasers. An OPO does not, however, need any organic dye or wavelength-dispersive element because the laser light is being produced in a nonlinear crystal that splits the incoming photons into two (whose energies thus sum up to that of the incoming photon). The two beams of light produced are referred to as signal and idler beams and have wavelengths that are above and below twice the wavelength of the incoming light, respectively. Pumped with the third harmonics of a Nd:YAG laser (355 nm), an OPO can therefore produce tunable laser light in two wavelength regions (approximately 410–690 nm and 730 nm–2 µm). Equipped with a frequency-doubling crystal, these lasers are tunable by computer control over the entire wavelength region of 220–2000 nm (with no need for any change of dye solution, etc.).

The output characteristics of an OPO depend greatly on the pump laser but in most situations are superior to those of dye lasers. Laser pulses with energies of several tens of millijoules can normally be produced in the entire visible part of the spectrum, whereas pulse energies of several millijoules can be produced in the UV region. Because there is no dispersive element in an OPO, the bandwidth is mainly determined by the bandwidth of the pump laser. In order to produce laser light with a sufficiently narrow bandwidth, the pump laser should therefore also have a narrow bandwidth. This requires the use of injection-seeded pump lasers (e.g. a Nd:YAG laser whose light is originally produced by a narrow-band diode laser system placed in the cavity).

2.3 Conclusions

In conclusion, modern tunable laser sources can produce narrow-band light with significantly higher spectral irradiance than any conventional light source. Because a narrow frequency width and a high spectral irradiance are the basis for the high selectivity and sensitivity, respectively, of laser-based spectroscopic techniques, laser light can, if correctly used, enhance the signal-to-noise (S/N) ratio and increase the detection power in many types of applications, not least for analytical spectrometry.

3 INTERACTION OF ATOMS WITH LASER LIGHT

Although all laser-based spectroscopic techniques have in common the fact that narrow-band laser light is used to interact selectively with the analyte atoms, the interaction has a different objective for the three techniques.
scrutinized in this review: fluorescence, ionization and absorption. Although the main aim of the fluorescence technique is to produce as many fluorescence photons as possible, the ionization techniques strive for ionizing (selectively) as large a fraction of the analyte atoms as possible. The common denominator for these two techniques is therefore to excite as many analyte species as possible. The absorption techniques, on the other hand, strive for minimizing, by the use of various modulation techniques, the amount of noise that affects the measurements, rather than maximizing the number of excited analyte species. This necessarily leads to different theoretical descriptions of, on the one hand, the fluorescence and ionization techniques and, on the other hand, the absorption technique. In this section we will give a theoretical basis for the fluorescence and ionization techniques (in terms of the number of atoms excited); the theoretical description of the absorption techniques is referred to in section 6.

### 3.1 Fluorescence and Ionization

Before scrutinizing in detail how free atoms interact with laser light, let us first conclude which entities are of importance for the fluorescence and ionization techniques.

For the fluorescence technique, fluorescence is assumed to be measured from an excited level, here denoted level 2 for simplicity, down to a lower-lying level, denoted 1 (see Figure 1). The rate of photon emission from level 2 to level 1 in a volume \( V \) of excited atoms, \( \dot{N}_{ph}(t) \), is directly proportional to the number density of atoms in the excited state, \( n_2(t) \) (in units of \( \text{m}^{-3} \)), as shown in Equation (1):

\[
\dot{N}_{ph}(t) = V A_{21} n_2(t) \tag{1}
\]

where \( A_{21} \) represents the spontaneous emission rate from level 2 to level 1. The number of fluorescence photons emitted over a time \( t \), \( N_{ph}(t) \), can then be written as in Equation (2):

\[
N_{ph}(t) = \int_{0}^{t} \dot{N}_{ph}(t') \, dt' = VA_{21} \int_{0}^{t} n_2(t') \, dt' \tag{2}
\]

When ionization techniques are used, the entity of interest is the number of atoms that are ionized as a consequence of the laser illumination. As will be discussed in detail below, a prerequisite for the LEI technique is that there exists a thermal collisional ionization rate in the medium.\(^{(39)}\) In such a system, species in all states, \( i \) (and not only those in one particular state, as is the case for the fluorescence technique), will contribute to the thermal ionization rate, \( \dot{N}_{ion}(t) \), by their own (state-specific) collisional ionization rate, \( k_{i,ion} \). This implies that the total ionization rate can be written as in Equation (3):

\[
\dot{N}_{ion}(t) = \int_{0}^{t} \dot{N}_{ion}(t') \, dt' = V \sum_{i} k_{i,ion} n_i(t) \tag{3}
\]

For the RIS technique, for which photoionization most often is the dominating ionization mechanism,\(^{(11,41)}\) Equations (3) and (4) are still valid, with the only difference that the state-specific collisional ionization rate, \( k_{i,ion} \), needs to be interpreted as a state-specific photoionization rate, \( \phi_{i,ion} \), given by Equation (5):

\[
\phi_{i,ion} = \frac{\sigma_{i,ion}}{\nu} \tag{5}
\]

where \( I \) is the irradiance of the laser light (in units of \( \text{W m}^{-2} \)), \( \sigma_{i,ion} \) is the cross-section for photoionization from state \( i \), and \( \nu \) is the photon energy. The sum in Equation (4) should in this case run over all states that have an energy deficit to ionization limit that is smaller that the photon energy.

The presentation below has, however, mostly been restricted to techniques utilizing atmospheric pressure atomizers, such as flames, furnaces or plasmas, owing to their versatility and user-friendliness. This presentation will therefore focus more upon the situation for the LEI technique than the RIS technique (although the two techniques have many aspects in common) and thereby consider the ionization to be mainly caused by collisions. The reader is referred to the literature for a more detailed presentation of the theory for the RIS technique.\(^{(19)}\)

Hence, in order to estimate the number of photons emitted, \( N_{ph}(t) \), or the number of ions created, \( \dot{N}_{ion}(t) \),
from a given atomic system we need to determine the number densities (often referred to as the “populations”) of the excited states ($n_2(t)$ for the LIF technique and all $n_i(t)$ for the LEI technique).

As will be shown by the treatment below, in order to get a high sensitivity for the LIF technique it is often sufficient to excite the analyte with light from one laser (commonly referred to as one-step excitation). One-step excitations in two- or three (multi)-level atoms will therefore be covered first. A one-step excitation is, however, normally not the optimum situation for the LEI technique. In addition, this presentation will therefore be covered briefly thereafter. As will be discussed further below, two-step excitations can, under certain conditions, be beneficial also for the LIF technique. In addition, this presentation will be based upon the rate equation formalism and be restricted to the cases when the laser light is tuned exactly on resonance. This implies, among other things, that there will be virtually no discussion about the spectral shape of various excitation profiles.

3.2 Two-level Atoms

3.2.1 General Description of a Two-level System Exposed to a Resonant Laser Field

When laser light is tuned to a transition between the ground state and an excited state in an atom and the atomic structure is such that it is warranted to neglect the presence of other excited levels, the analyte atoms can often be described as two-level atoms. The two-level model can well be used, for example, for descriptions of excitations of the first resonant transition in elements that have no fine-structure splitting of any of the laser-connected levels and very few other excited states close to the laser-connected state (as, for example, is the case for Zn, Cd and Hg). The two-level model is sometimes appropriate also for other more complicated atomic systems.

3.2.1.1 Rate Equations for a Two-level System

The excitation process in a two-level atom exposed to resonant laser light (as displayed in Figure 1) can be modeled in the so-called rate equation formalism as depicted in Equations (6) and (7):

$$\frac{dn_2}{dt} = B_{12}I_\lambda n_1 - (B_{21}I_v + R_{21})n_2 \quad (6)$$

$$n_{\text{atom}} = n_1 + n_2 \quad (7)$$

where $B_{12}I_\lambda$ and $B_{21}I_v$ represent the light-induced excitation and de-excitation rates between the two laser-connected states, respectively; $R_{21}$ represents all the nonlight-induced de-excitation processes (in this case the sum of the spontaneous de-excitation processes, denoted $A_{ij}$, and the collisional de-excitation rate, denoted $k_{ij}$); and $n_{\text{atom}}$ is the total number density of (neutral) analyte atoms in the interaction region.

The light-induced excitation and de-excitation rates, $B_{12}I_\lambda$ and $B_{21}I_v$, consist of a product of the Einstein coefficients for absorption and stimulated emission ($B_{12}$ and $B_{21}$, respectively, in units of m$^2$ Hz J$^{-1}$) and the spectral irradiance of the light (in units of W m$^{-2}$ Hz$^{-1}$). The Einstein coefficients for absorption and emission are related to the rate of spontaneous emission, $A_{21}$, by the relations shown in Equation (8):

$$B_{12} = \frac{g_2}{g_1} B_{21} = \frac{g_2^3}{g_1 8\pi lhc} A_{21} \quad (8)$$

where $\lambda$ is the wavelength of the light, $h$ is Planck’s constant, $c$ is the speed of light, and $g_1$ and $g_2$ are the degeneracies of the two levels.

3.2.1.2 Solution of the Rate Equations

When solving rate equations, it is often convenient to work with normalized entities, i.e. to define the fraction of neutral atoms in a state $i$ as $\tilde{n}_i$ according to Equation (9):

$$\tilde{n}_i = \frac{n_i}{n_{\text{atom}}} \quad (9)$$

Using this nomenclature, the fraction of neutral atoms in state 2 can be written according to Equation (10):

$$\tilde{n}_2(t) = \tilde{n}^{\text{sat}}_2 \frac{B_{12}I_\lambda}{B_{12}I_\lambda + \tilde{n}^{\text{sat}}_2 R_{21}} \left(1 - \exp \left(\frac{-t}{\tau}\right)\right) \quad (10)$$

where $\tilde{n}^{\text{sat}}_2$ and $\tau$ are the saturation population fraction of level 2 (Equation 11) and the time constant for establishment of a steady state (i.e. a time-independent situation; Equation 12) respectively.

$$\tilde{n}^{\text{sat}}_2 = \frac{g_2}{g_1 + g_2} \quad (11)$$

$$\tau = \frac{\tilde{n}^{\text{sat}}_2}{B_{12}I_\lambda + \tilde{n}^{\text{sat}}_2 R_{21}} \quad (12)$$

This implies that when the two-level system is exposed to a laser excitation, the fraction of excited atom will increase with time (in an exponential manner with a time constant $\tau$) towards a steady-state value given by the product of the two first factors of Equation (10). The product of these two entities is therefore referred to as the steady-state excitation population fraction. In order to estimate a typical time constant for the establishment of a steady-state condition as well as the steady-state excitation population fraction of an atomic system exposed to laser light under conditions typically
prevailing in the most commonly used atomizers, the various rates involved need to be estimated.

3.2.1.3 Typical Excitation and De-excitation Rates
Typical values for the spontaneous emission rate, $A_{21}$, range generally from $10^7 \text{s}^{-1}$ to a few times $10^8 \text{s}^{-1}$. This implies that the Einstein coefficients for absorption and stimulated emission, $B_{12}$ and $B_{21}$, are of the order of $3 \times 10^{10} - 3 \times 10^{11} \text{ m}^2 \text{ Hz J}^{-1}$ for a UV transition (at 250 nm), assuming equal degrees of degeneracy of the two levels. Because typical spectral irradiances of UV light from pulsed laser systems are in the 0.1–1 W m$^{-2}$ Hz$^{-1}$ range (see Table 1), typical absorption and laser-induced stimulated emission rates for pulsed laser excitations are often in the gigahertz range. For example, excitation of atoms using a UV transition with a spontaneous emission rate of $10^8 \text{s}^{-1}$ using laser pulses with a 10-µJ pulse energy, a 10-ns duration and a spectral width of 10 GHz, focused down to a diameter of 6 mm, gives rise to an excitation rate around 1 GHz. The corresponding excitation rate for a similar transition in the visible region can often become one to three orders of magnitude larger, owing to larger $B$-factors and higher laser pulse energies.

The collisional de-excitation rates depend on factors such as pressure, temperature and type of collision partner, and differ therefore among various atomizers. Typical collision rates between radiatively coupled levels in atoms in inert gas atmospheric pressure atomizers, e.g. flames with Ar as buffer gas, often referred to as a high quantum efficiency flame, or electrothermal atomizers (ETAs), are often slightly below the gigahertz range. In air-supported atomizers, the rates are often in the low gigahertz range, with particularly high values for rates between closely spaced states. This implies that collisional de-excitation rates often can dominate over spontaneous emission (especially in high collisional media such as flames). On the other hand, because light-induced excitation and de-excitation rates often can be well into the gigahertz range, they can, in turn, often exceed all nonlaser-connected de-excitation rates in the system.

3.2.1.4 Justification of the Steady-state Approximation
Because excitation rates often are in the gigahertz range when pulsed laser systems are used, Equation (12) shows that the time constant for establishment of a steady-state condition in a two-level system becomes very short, often significantly less than 1 ns. A couple of examples of the time dependence of the population of the upper level of a two-level system are shown in Figure 2(a) for two different laser excitation rates (0.5 and 5 GHz, respectively) for a “typical” situation with a nonlaser-induced de-excitation rate of 1 GHz. Because most lasers used for LIF and LEI spectrometry are pulsed with pulse lengths in the 5–30 ns range, and the saturated excited fraction of atoms reaches its steady-state value within about 1 ns, one can conclude that any two laser-connected levels will reach their steady-state values within a fraction of the pulse length. This warrants the often-used approximation (valid for pulses whose duration is significantly longer than the time constant $\tau$) that the number densities of atoms in the two laser-connected levels can be considered to be locked to each other (to their steady-state population fractions) during the laser illumination period.

3.2.1.5 Optical Saturation
Moreover, Equation (10) above shows that the steady-state number density
of excited atoms in the interaction volume will be proportional to the laser spectral irradiance (i.e. to the intensity) for low light levels and that it will level off towards a plateau for higher light levels, i.e. the saturated excited fraction of atoms (given by \( n_{21}^{\text{sat}} \)) shown in Figure 2(b). This particular type of population density versus irradiation is called a saturation curve. The reason for the leveling off of the population density for high light levels is that the rate of stimulated emission dominates the combined rate of spontaneous emission and collisional de-excitation. When this takes place, the system is said to be optically saturated. The second term in the denominator of Equation (12), i.e. \( n_{21}^{\text{sat}} R_{21} \), is called the saturation rate (or saturation parameter). This rate has an important role when laser-based techniques are used for diagnostic purposes.\(^{60}\) The low- and high-intensity asymptotes are drawn with dashed lines in Figure 2(b). The saturation rate (which is the rate at which these two asymptotes meet, or where the saturated excited fraction of atoms reaches half of its maximum value) is also indicated for clarity.

The intensity (or spectral irradiance) for which the excitation rate is equal to the saturation parameter is termed saturation intensity (or spectral saturation irradiance).\(^{61\text{--}68}\) The spectral saturation irradiance for a two-level system can be written according to Equation (13):

\[
P_{\text{sat}} = \frac{n_{21}^{\text{sat}}}{B_{12}} R_{21} = \frac{g_1}{g_1 + g_2} \frac{8\pi \hbar c}{\lambda^3} \frac{1}{Y_{21}}
\]

where \( Y_{21} \) represents the fluorescence yield (also referred to as quantum yield in the literature). The fluorescence yield can be defined as the ratio of the spontaneous emission rate to the total nonlaser-induced de-excitation rate (Equation 14), i.e.

\[
Y_{21} = \frac{A_{21}}{R_{21}} = \frac{A_{21}}{A_{21} + k_{21}}
\]

and is an entity of importance for the amount of fluorescence emitted from a system (see discussion below).

Because the collisional de-excitation rate differs among various atomizers (and depends on the running conditions to a certain extent), the fluorescence yield and thereby the saturation spectral irradiance will differ. Depending on details of the transitions and the collision partners, the fluorescence yield can range from a few percent to values close to unity in atmospheric pressure atomizers.\(^{69}\) As an example, Hannonford reported on fluorescence yields in the 0.24–0.87 range for the strongest resonance lines of a number of elements (Li, Na, K, Rb, Cs, Ga, In, Tl, Au, Sn, Pb, etc.) in an argon-diluted stoichiometric oxygen–hydrogen flame.\(^{69}\) Fluorescence yields in this range give “typical” spectral saturation irradiances for a two-level system in the \(10^{-4}–10^{-3} \text{ W m}^{-2} \text{ Hz}^{-1}\) range for UV transitions and in the \(10^{-3}–10^{-2} \text{ W m}^{-2} \text{ Hz}^{-1}\) range for transitions in the visible spectrum. By comparison with the “typical” spectral irradiance from pulsed as well as continuous-wave laser systems (see Table 1), one can conclude that optical saturation of a two-level system in atmospheric pressure atomizers can easily be obtained with light from pulsed laser systems. For a continuous-wave system, on the other hand, optical saturation is normally only achieved with some degree of focusing of the laser beam.

### 3.2.2 Fluorescence from a Two-level System

Let us define the number of photons emitted per atom under a time \( t, N_{\text{ph}}(t) \), according to Equation (15):

\[
N_{\text{ph}}(t) = \frac{N_{\text{ph}}(t)}{N_{\text{atom}}}
\]

where \( N_{\text{atom}} \) is the number of illuminated atoms (given by \( V n_{\text{atom}} \)). The rate of photon emission per atom, \( \tilde{N}_{\text{ph}}(t) \), can then be written (using Equations 1, 9 and 15) according to Equation (16):

\[
\tilde{N}_{\text{ph}}(t) = A_{21} n_{21}(t)
\]

#### 3.2.2.1 Fluorescence from an Unsaturated Two-level System

The rate of photon emission per atom, for a two-level system exposed to low light levels (i.e. for laser light intensities below the saturation intensity, \( I_s \ll I_{\text{sat}} \)), under steady-state conditions (i.e. for \( t \gg \tau \)), can then (using Equations 10, 14 and 16) be expressed as shown in Equation (17):

\[
\tilde{N}_{\text{ph}} = Y_{21} B_{12} r
\]

This shows that the rate of photon emission per atom from a two-level system (illuminated by a laser whose duration is longer than \( \tau \)) is independent of time and that it depends, in the unsaturated case, on the product of the excitation rate, \( B_{12} r \), and the fluorescence yield, \( Y_{21} \). The number of photons emitted per atom under a time \( t \) is therefore given by Equation (18):

\[
N_{\text{ph}}(t) = Y_{21} B_{12} r t
\]

Although these expressions look handy, they show that the fluorescence technique indeed has a weakness. The fact that the signal depends on the fluorescence yield implies that the sensitivity of the LIF technique (the number of photons produced from a given amount of
3.2.2 Fluorescence from a Saturated Two-level System

For a high laser light irradiance (i.e. for \( I_\text{e} \gg I_\text{sat} \)), the fraction of atoms excited (and thereby also the number of emitted photons) becomes independent of the laser light intensity as well as of the quenching rate. This implies that the rate of emission of fluorescence photons per atom under saturated conditions can be written as shown in Equation (19):

\[
\dot{N}_\text{ph} = \dot{n}_\text{sat}^2 A_{21} \tag{19}
\]

The number of photons emitted per atom from a saturated two-level system under a time \( t \) is therefore given by Equation (20):

\[
\dot{N}_\text{ph}(t) = \dot{n}_\text{sat}^2 A_{21} t \tag{20}
\]

This implies that the number of photons emitted per (two-level) atom can be made independent of the fluorescence yield as well as the laser irradiation under saturated conditions.

3.2.2.3 Number of Photons Emitted per Two-level Atom

Using "typical" numbers from the discussion above, one finds that the number of photons emitted per two-level atom, excited by light from an excimer system under saturated conditions, can be close to unity (e.g. for a situation with a spontaneous emission rate of \( 10^8 \text{s}^{-1} \), equal degeneracies of the two levels, and a pulse duration of 20 ns). The number of photons emitted per atom under saturated conditions will exceed unity for sufficiently long laser illumination times (i.e. for \( t > (\dot{n}_\text{sat}^2 A_{21})^{-1} \)).

The interaction time for continuous-wave illumination is often determined by the time the atoms spend in the interaction volume, which, in turn, depends on properties of the particular instrumentation used: primarily the atom drift velocity and dimensions of the laser beam. The number of photons emitted per two-level atom can therefore significantly exceed unity for continuous-wave excitations (even if optical saturation is not always reached). However, because illumination with continuous-wave light implies that detection has to be performed over long periods of time, more noise will be detected than under pulsed conditions. This does not necessarily imply, therefore, that the detectability of atoms with continuous-wave light is better than with pulsed laser sources.

3.2.3 Practical Aspects of Optical Saturation

3.2.3.1 Analytical Aspects of Optical Saturation

The advantages of optical saturation are that it maximizes the fluorescence signal, minimizes the signal fluctuations (which implies that it improves on the precision), and makes the signal independent of the fluorescence yield (improves on the accuracy). Although optical saturation seems to solve many problems related to quantitative spectrometry, it has some drawbacks. The main disadvantage is that optical saturation can deteriorate the S/N ratio by introducing high levels of scattered light or background signals. The phenomenon of optical saturation also leads to a broadening of the profiles when scanning the laser wavelength. This is referred to as saturation broadening, as has been reviewed in detail in the literature. It has therefore been suggested that a suitable working methodology for the fluorescence technique (when applied to analytical applications) is to work at laser intensities close to (but not really at) optical saturation.

3.2.3.2 Diagnostic Aspects of Optical Saturation

It was prophesied earlier that the LIF technique, owing to the existence of optical saturation as well as the tunability, narrow bandwidth and high directionality of the laser light, also has a unique diagnostic capability. Numerous publications have therefore analyzed the properties of the optical saturation phenomenon in detail. It should be possible, for example, to use the concept of saturated fluorescence to determine a variety of physical or chemical entities in the system under study. Such an experiment would consist of operating the laser at a sufficiently high spectral irradiance (so that optical saturation is guaranteed) and measuring the amount of fluorescence. By then attenuating the laser light in known fractions (e.g. using neutral density filters) and measuring the fluorescence, it should be possible to determine the saturation spectral irradiance. Entities such as the fluorescence yield, the de-excitation rate, or the quenching cross-section could then be evaluated from the saturation spectral irradiance through Equation (13).

History has shown, however, that the analysis of the experimental data is not always as unambiguous as suggested above. The reason is that the saturation curves very seldom conform to the predicted ideal saturation curve predicted by Equation (10). Instead, experimentally measured saturation curves often continue to increase with increasing light levels instead of reaching the irradiance-independent plateau. There are
numerous reasons for this. Two important ones are spatial and temporal nonhomogeneities of the laser beam. A laser beam with a higher intensity in its center part than in its periphery will saturate the atoms in its center parts to a larger extent that in its periphery. A pulse with a temporal inhomogeneity will saturate the atoms more strongly during its high-intensity part than in its weak-intensity parts. Other possible reasons for nonideal saturation curves are that the atomic system is not sufficiently well represented by simple two-level atoms or that the steady-state condition is not valid. For further details, the reader is referred to an excellent review by Alkemade about anomalous saturation curves in LIF.

3.2.4 Limitations of the Two-level Representation

The situation described by this two-level model, in which the fluorescence is measured at the same transition wavelength as is used for the excitation, is referred to as resonance fluorescence. However, this means of detecting fluorescence has little practical use for the most demanding analytical applications because the detection system, which necessarily has to be tuned to detect fluorescence at the laser wavelength, has no possibility to reject scattered laser light (which originates from laser light being reflected at various surfaces or by particles or molecules in the atomizer). It is therefore of importance to find viable alternatives to resonance fluorescence. One such alternative is to excite the atoms to levels from which they can fluoresce at more than one wavelength. This implies that it is of importance to investigate to which extent other levels (i.e. nonlaser-connected levels) interact with the laser-connected levels. The following section is therefore concerned with an analysis of a multilevel atomic system, represented by various types of three-level system for simplicity, exposed to one laser field. This issue is thus of special importance to all modes of detection that are not well represented by a two-level system. A three-level model will also enable us to describe the most basic phenomena for the LEI technique. As will be apparent, the existence of various nonlaser-connected levels will significantly affect the atomic system (and thereby also the signal strength and the detection capability).

3.3 Multilevel Atoms Exposed to One Laser Field

3.3.1 General Description of a Three-level System Exposed to One Laser Field

3.3.1.1 Rate Equation System for a Three-level System Exposed to One Laser Field

The rate equations for a three-level atomic system exposed to one laser field connecting levels 1 and 2, and with the nonlaser-connected level denoted 2′, can be written as Equations (21–23):

\[
\frac{dn_1}{dt} = (B_{12}I_\nu + R_{12})n_1 - (B_{21}I_\nu + R_{21} + R_{22})n_2 + R_{22}n_2
\]  
\[
\frac{dn_2}{dt} = R_{12}n_1 + R_{22}n_2 - (R_{21} + R_{22})n_2
\]  
\[
\frac{dn_{atm}}{dt} = n_1 + n_2 + n_2
\]

where the various \( R_{ij} \), as before, represent the sum of the collisional de-excitation rate, \( k_{ij} \), and the spontaneous emission rate, \( A_i \), for the case of dipole-allowed exothermic transitions, but only the collisional excitation or de-excitation rates (i.e. \( k_{ij} \)) for the other transitions.

3.3.1.2 Various Types of Three-level Systems

Although it is possible to solve the set of rate equations once and for all, it is more illustrative and often more convenient to solve the system under a few typical conditions so that the specific influence of each type of nonlaser-connected level can be appraised clearly. There are three conceptually different three-level systems of specific interest for the LIF and LEI techniques, namely when the nonlaser-connected state is:

1. representative of the huge number of highly excited states (Rydberg levels) that exist in all atoms (see Figure 3a);
2. an excited level in close proximity to the upper laser-connected level, which also is radiatively coupled to the ground state, e.g. the 3P-states in alkali atoms (see Figure 3b);
3. a metastable state, i.e. one that is radiatively coupled to the upper laser-connected level but not to the ground state, e.g. the upper fine-structure component of the ground configuration in elements such as Al, In, Ga and Tl (see Figure 3c).

These three systems will be referred to below as cases 1, 2 and 3 respectively.

3.3.1.3 Three-level System with a High-lying Nonlaser-connected State

The influence of a highly excited state (case 1) or a state in close proximity to the upper laser-connected level (case 2) can be investigated by solving the set of rate equations (Equations 21–23) under steady-state conditions. The fraction of atoms in the two excited states (under steady-state conditions) can be written according to Equations (24) and (25):

\[
\bar{n}_2 = \frac{B_{12}I_\nu}{B_{12}I_\nu + \bar{n}_{2\text{sat}}(R_{21} + R_{21}X_2)}
\]  
\[
\bar{n}_2 = \frac{B_{12}I_\nu}{B_{12}I_\nu + \bar{n}_{2\text{sat}}(R_{21} + R_{21}X_2)}
\]
respectively, given by Equations (26) and (27):

\[ \frac{N_{1}}{N_{0}} \]

where \( r_{2} \), in turn, represents the ratio of the filling and emptying rates of the nonlaser-connected level (Equation 28):

\[ r_{2} = \frac{R_{22}^{'}}{R_{21} + R_{22}'} \]  

These expressions show clearly that not only the density of atoms in the upper laser-connected level is being affected by the laser excitation but also the densities of atoms in the nonlaser-connected levels (represented by level 2') are being influenced. This implies, among other things, that although the laser excitation only induces a transition to one specific state, LIF will in fact be emitted from atoms in virtually all excited states. This opens up viable alternatives to resonance fluorescence.

The fraction of atoms in a specific nonlaser-connected excited state can be calculated by inserting the appropriate values for all the quantities involved. The collisional excitation rates can be related to the corresponding de-excitation rates by the concept of detailed balance, as shown in Equation (29):

\[ k_{ij} = \frac{g_{i}}{g_{j}} \exp \left( \frac{-\Delta E_{ij}}{kT} \right) k_{ji} \]  

where \( \Delta E_{ij} \) is the energy difference between the two states for which \( E_{i} > E_{j} \) (in J), \( k \) is Boltzmann's constant and \( T \) is the temperature (in K). However, because not all such rates used to be known, some approximations or generalizations are often used.

One way to estimate the fraction of atoms in a specific nonlaser-connected excited state for cases 1 and 2 is to assume that the collisional rates from level 2' dominate over any possible spontaneous emission rate from that particular level and that the decay of the nonlaser-connected level to the ground state is smaller than that to the excited state (i.e. \( R_{21} < R_{22} \)). One then finds that \( \chi_{2} \) takes a particularly simple form, as shown in Equation (30):

\[ \chi_{2} = \frac{g_{2}^{\prime}}{g_{2}} \exp \left( \frac{-\Delta E_{22}^{'}}{kT} \right) \]  

Equation (27) then shows that the fraction of atoms in highly excited states (i.e., those that have a large energy deficit to the upper laser-connected level; case 1 atoms) will be significantly lower than that of the upper laser-connected level (because \( \chi_{2} \ll 1 \)).

For atoms with an excited level in close proximity to the upper laser-connected level (for which the energy deficit normally is small), on the other hand, i.e., for case 2 atoms, the fraction of atoms in this nonlaser-connected level can be comparable to that of the upper laser-connected level (because \( \chi_{2} \approx 1 \)).
3.3.1.4 Three-level System with a Metastable State

The third case of special importance (case 3) is when the nonlaser-connected state represents a metastable state (i.e. a state that is radiatively coupled to the upper laser-connected level but not to the ground state). Elements that have a metastable state are, for example, those with fine-structure splitting of the ground configuration, e.g. Al, In, Ga and Tl, or other low-lying states of the same parity as the ground state, e.g. Cu, Ag and Au. It has been found that the actual lifetimes of metastable states are significantly longer than the typical pulse lengths from the most commonly used laser systems (µs versus ns), even in such highly collisional media as atmospheric pressure atomizers.\(^{(72,81–85)}\)

These long lifetimes preclude any steady-state condition to be established with the nonlaser-connected level within the laser pulse duration.\(^{(59,63)}\) The system of rate equations (Equations 21–23) therefore needs to be solved with its full temporal behavior for atoms with metastable states.\(^{(59,63,72,73,85)}\)

A simplified solution for the population of the uppermost laser-connected level in the presence of a lower-lying metastable level can be obtained by assuming that a steady-state condition first is established between the two laser-connected levels within a fraction of the pulse length (following the discussion in section 3.2.1.4). Under this assumption, atoms in the upper laser-connected level will decay to the metastable state at such a rate that the relation between the populations of the two laser-connected levels is not altered.\(^{(72,73)}\)

The fraction of atoms in the upper laser-connected level then has a time dependence that can be written as shown in Equation (31):

\[
\bar{n}_2(t) = \bar{n}^{ss}_2 1 + \left(\frac{\bar{n}^{ss}_2}{\bar{n}^{ss}_2} - 1\right) \exp\left(-\frac{t}{\tau_m}\right)
\]

where \(\bar{n}^{ss}_2\) is the fraction of atoms in the second level directly after the onset of steady state between the two laser-connected levels but before any substantial population has been transferred to the metastable state (i.e. \(\bar{n}_2(t) \approx \bar{n}^{ss}_2\) when \(t \approx 0\)). \(\bar{n}^{ss}_2\) is the steady-state value of the fraction of atoms in level 2 after infinite time (i.e. \(\bar{n}_2(t) \approx \bar{n}^{ss}_2\) when \(t \to \infty\)) and \(\tau_m\) is the decay time of the laser-connected pair of transitions into the metastable state. These three entities are given by Equations (32–34):

\[
\bar{n}^{ss}_2 = \frac{\bar{n}^{sat}_2}{B_{12}I_e} B_{12}I_e + \bar{n}^{sat}_2(R_{21} + R_{22})
\]

\[
\bar{n}^{sat}_2 = (\chi_2)^{-1} \frac{B_{12}I_e}{B_{12}I_e + (\chi_2)^{-1}(R_{21} + R_{22})}
\]

\[
\tau_m = \frac{1}{\bar{n}^{sat}_2 R_{22}}
\]

where \(\bar{n}^{sat}_2\) and \(\chi_2\) are the saturation population fraction in a two-level system (Equation 11) and the ratio of the filling and emptying rates of the nonlaser-connected level (Equation 28), respectively. It important to realize that \(\chi_2 \ll 1\) (and thereby \(\chi_2^2 \ll 1\)) for a metastable state, which implies the condition in Equation (35):

\[
\bar{n}^{sat}_2 \gg \bar{n}^{ss}_2
\]

which, in turn, and in practice, implies that the fraction of atoms in the upper laser-connected level rapidly (in this approximation, instantaneously after the onset of the laser excitation) reaches a value similar to what would be the case if there were not any metastable state \(\bar{n}^{ps}_2\) (for saturated condition, the fraction of atoms in this state is momentarily \(\bar{n}^{ss}_2\)). The decay to the metastable state will, however, rapidly drain this population of the upper laser-connected state. This is done with a rate roughly given by the decay rate from the upper laser-connected level to the metastable state (\(R_{22}\)). Because this rate can be substantial, this implies that the fraction of atoms in the upper laser-connected level can decay to significantly lower values even within the duration of a laser pulse from a pulsed laser system. For excitation with a continuous laser light, a steady-state condition given by \(\bar{n}^{ss}_2\) will prevail. The fraction of atoms in the upper laser-connected level will, under these conditions, only be a fraction (\(\chi_2^{-1}\)) of the value reached momentarily directly after onset of the excitation.

3.3.1.5 Conclusions

This analysis of a three-level system exposed to a single laser field shows clearly that each nonlaser-connected level (irrespective of whether it is a Rydberg state, a closely situated state, or a lower-lying metastable state) influences the populations of the laser-connected levels as well as the requirement of optical saturation (and thereby also the fluorescence and ionization rates). It is not possible, however, to investigate the consequences of this in any detail here. The reader is referred to the literature for a more thorough treatment.\(^{(62,63,73,85,86)}\)

It can be concluded, however, that the multilevel structure of some atoms explains some (but far from all) of the unusual findings about optical saturation in the literature. Bolshov et al., for example, found that the \(6p^2 3P_0 – 6p 7s 3P_1\) transition (at 283.31 nm) in Pb atoms in a GF became saturated at a laser irradiance of 20 kW cm\(^{-2}\), whereas the \(3d^6 4s^2 4d^1 5D_4 – 3d^7 4p^2 F_3\) transition (at 296.69 nm) in Fe showed no sign of saturation up to 300 kW cm\(^{-2}\).\(^{(85)}\)

As can be concluded from a comparison with the treatment of the two-level system above, both of these saturation irradiances are larger than expected from a simple two-level atom model, possibly indicating influences of nonlaser-connected levels.

The fact that atoms will be promoted also to nonlaser-connected states by the laser excitation has significant but
3.3.2 Implications of Nonlaser-connected Levels for Laser-induced Fluorescence

3.3.2.1 Laser-induced Fluorescence from a Three-level System with a Nonlaser-connected Rydberg State (Case 1) Equations (24–27) and (30) show that the number density of atoms in highly excited nonlaser-connected states is significantly smaller than that of the upper laser-connected level. The density of atoms decreases by one order of magnitude for each 4000 cm\(^{-1}\) that separates the two excited states in an atomizer with a temperature of 2500 K. Hence, although LIF in principle will be emitted from virtually all excited states, very few photons will be emitted from excited levels significantly above the upper laser-connected level. Hence, highly excited nonlaser-connected levels generally play a small or insignificant role in the LIF technique.

3.3.2.2 Laser-induced Fluorescence from a Three-level System with a Split Upper Level (Case 2) The situation is different for those atoms that have a nonlaser-connected level in close proximity to the upper laser-connected level. Two levels in close proximity not only have a small energy difference, i.e. \(\Delta E_{ij} \ll kT\), but often they also have a fast mixing rate, i.e. \(R_{22} \gg R_{21}\). This justifies the assumption above, leading to Equation (30), which, in turn, implies that \(\chi_2\) often takes a value equal to the ratio of the degeneracy factors of the two levels, i.e. \(g_2/g_2\). This implies, furthermore, that the population density on the nonlaser-connected level, in fact, can be comparable to (or even exceed) that of the upper laser-connected level. If this nonlaser-connected level also is radiatively coupled to the ground state, this implies that LIF often can be detected from levels in close proximity to the upper laser-connected level without any significant loss of signal strength. This is of special importance for those elements that have a ground state with no fine-structure splitting, or no other suitable low-lying levels to which fluorescence can be measured from the upper laser-connected level (for which resonant fluorescence otherwise would have been the only possibility). In conclusion, detection of fluorescence from nonlaser-connected excited states in close proximity to the upper laser-connected level might often be a viable alternative to resonance detection.

3.3.2.3 Laser-induced Fluorescence from a Three-level System with a Metastable State (Case 3) The rate of emission of photons per atom for a system with a metastable state is given directly by the time evolution of the fraction of atoms in the upper laser-connected level (Equation 31) and can therefore, in general, be written according to Equation (36):

\[
\frac{\bar{N}_{ph}(t)}{N} = \bar{n}_2^{\text{sat}} A_{22} \left( 1 + \frac{\bar{n}_2^{\text{sat}}}{\bar{n}_2^{\text{st}}} - 1 \exp \left( -\frac{t}{\tau_m} \right) \right)
\]

This simplifies considerably under saturated conditions to the form given in Equation (37):

\[
\frac{\bar{N}_{ph}(t)}{N} = \frac{A_{22}}{\chi_2} \left( 1 + \frac{\bar{n}_2^{\text{sat}}}{\bar{n}_2^{\text{st}}} \exp \left( -\frac{t}{\tau_m} \right) \right)
\]

where \(\chi_2 \gg 1\) (and hence \(n_2^{\text{sat}} \gg n_2^{\text{st}}\)) has been assumed for a metastable state. This implies that the rate of emission of fluorescence from a metastable system rapidly decreases following the onset of laser illumination, as shown in Figure 4.

Although the initial rate of emission of fluorescence photons from a saturated metastable system (i.e. for \(0 < t \ll \tau_m\)) is given by Equation (38):

\[
\frac{\bar{N}_{ph}(t)}{N} \approx 0^+ = \frac{A_{22}^{\text{sat}}}{\chi_2^{\text{sat}}} \approx A_{22}^{\text{sat}}
\]

which is similar to that of a saturated two-level system, the rate of emission becomes significantly lower when the system has reached steady-state conditions (i.e. for

![Figure 4](image_url)
under pulsed conditions is limited to the number of photons emitted per atom from this atomic system. This implies that the photon emission rate will be significantly smaller for continuous-wave excitations than for pulsed excitations. Because no steady-state condition will be established within the time period of a laser excitation from a pulsed laser, it is more appropriate to discuss the concept of the number of emitted fluorescence photons per atom within a time period \( t \) of laser excitation, \( N_{ph}(t) \), according to Equation (2). One then finds that \( N_{ph}(t) \) can be written as shown in Equation (40):

\[
N_{ph}(t) = N_{pss} \left\{ \left( 1 - \frac{N_{pss}^{ss}}{N_{pss}} \right) \tau_m - \exp \left( -\frac{t}{\tau_m} \right) \right\} A_{22'}
\]

(40)

for a system with a metastable state. This expression again simplifies under pulsed, saturated conditions, as shown in Equation (41):

\[
N_{ph}(t) = Y_{22'} \left( 1 - \exp \left( -\frac{t}{\tau_m} \right) \right)
\]

(41)

where \( \tau_m \), as above, is the decay time of the laser-connected pair of transitions given by Equation (34) and we again have used \( \chi_{2'} \gg 1 \) for a metastable state, assumed that the fluorescence is measured primarily over the most intensive part of the fluorescence pulse (i.e. over a time period \( t \) that does not substantially exceed the lifetime of the metastable state) and introduced \( Y_{22'} \) as the fluorescence transition yield for the transition between the upper laser-connected level and the metastable state, defined according to Equation (42):

\[
Y_{22'} = \frac{A_{22'}}{R_{22'}}
\]

(42)

Equation (41) (see Figure 4) shows that the number of photons emitted per atom from this atomic system under pulsed conditions is limited to \( Y_{22'} \). This value is reached (within 63%) after a time equal to the decay time of the laser-connected pair of transitions, i.e. \( \tau_m \), which, in turn, is roughly given by the inverse of the decay rate from the upper laser-connected state to the metastable state. Because many decay rates are slightly below or in the low gigahertz range, it implies that the actual length of typical pulses from pulsed laser systems (5–30 ns) corresponds fairly well to an efficient detection of fluorescence from atoms with metastable states in atmospheric pressure atomizers. This implies that no atom with a metastable state can emit more than one photon per laser pulse under excitation with pulsed laser light. It also implies that the fluorescence yield for the entire detection process of atoms with metastable states is given by the fluorescence transition yield for the transition between the upper laser-connected level and the metastable state, \( Y_{22'} \). For continuous-wave excitations, on the other hand, atoms with metastable states give significantly poorer detectability because the number of photons per atom does not increase as much with increased illumination time as does the amount of noise detected.

### 3.3.3 One-step Excitation Laser-enhanced Ionization

The influence of the various nonlaser-connected levels will be somewhat different for the LEI technique.

#### 3.3.3.1 Ionization Through Nonlaser-connected Rydberg States

Although the high-lying levels play a minor role in the fluorescence technique, they are of major importance for the LEI technique. As stated above (near Equations 3 and 4), the total ionization signal depends on the ionization rate density, \( n_{ion} \), which in turn is given by a sum over all state-specific ionization rates. Adapting this reasoning to the current model with two excited states (one laser-connected and one not), we find that the ionization rate density can be written as shown in Equation (43):

\[
n_{ion}(t) = k_{2,ion} n_{2}(t) + k_{2',ion} n_{2'}(t)
\]

(43)

It is commonplace to assume that the collisional ionization rate scales in a similar way to that of exciting collisions between two bound states, as was discussed in proximity to Equation (29), i.e. as \( \exp(\Delta E_{ion}/kT) \), where \( \Delta E_{ion} \) is the energy deficit to the ionization limit. This implies that even without any detailed knowledge about each of the two ionization rate constants in the expression above, they can be related to each other (assuming that \( E_{2'} > E_2 \)) according to Equation (44):

\[
k_{2,ion} \approx k_{2',ion} \exp \left( \frac{\Delta E_{2'}}{kT} \right)
\]

(44)

This implies that although the collisional ionization rate constant from level 2 is smaller than that of level 2’ by the factor \( \exp(\Delta E_{22'}/kT) \), Equations (24–27) and (30) show that the population of level 2’ is smaller than that of level 2 by almost the same factor (given by \( \chi_{2'} \)), which is expressed as Equation (45):

\[
\tilde{n}_{2'} \approx \tilde{n}_{2'} \exp \left( \frac{\Delta E_{22'}}{kT} \right)
\]

(45)

This implies, in turn, that all excited levels whose populations have an approximate relation to the upper laser-connected level by the activation energy factor (i.e. as given by Equation 30) also contribute approximately...
equally to the total ionization rate. This can be interpreted as if the ionization simultaneously takes place through a large number of “channels”. Following the treatment above, it would be easy to conclude that all levels whose energy is higher than that of the upper laser-connected level would qualify for being such a channel.

However, this argument gives rise to a contradiction. Because there are, in principle, an infinite number of excited states above the upper laser-connected level, this model predicts that the ionization rate would be infinite. In reality this is, of course, not the case. It has been argued in the literature that atoms that are not too highly excited can (or will) exist in atmospheric pressure atomizers (one reason is that their size makes them very vulnerable in the highly collisional environment). It has therefore been found suitable to introduce a certain cutoff principal number, representing the highest excited state that can contribute to the ionization. This is equivalent to introducing an effective collisional ionization rate that would act from only one excited state, most conveniently the upper laser-connected level. Hence, although the excited atoms will redistribute rapidly among a large number of excited states due to collisions, all of which will have their own state-specific ionization rate, we will model LEI by an effective collisional ionization rate, $k_{\text{eff}}$, acting only from the upper laser-connected level, as shown in Equation (46):

$$n_{\text{ion}}(t) = k_{\text{eff}}^{\text{ion}}n_2(t)$$

### 3.3.3.2 Ionization Yield for One-step Laser-enhanced Ionization

The electrical field across the interaction region in LEI will rapidly separate ions from electrons. The recombination rate will therefore be insignificant in the upper laser-connected level. This shows that it is not possible in general to reach any high degrees of ionization from one-step LEI (unless the atoms have unusually low ionization limits).

3.3.3.3 Means to Improve on the Low Ionization Yield for One-step Laser-enhanced Ionization

An obvious remedy to this is to excite the atoms to levels closer to the ionization limit. Although this can be done by a one-step excitation using far-UV light, it has been found to be less suitable. One reason is that it is getting increasingly difficult to create far-UV photons the further down in wavelength one goes. Another reason is that far-UV photons have a greater tendency to give rise to background signals from flame molecules and concomitant elements than visible photons have (which thus would counteract the expected increase in S/N ratio). It has been found more convenient (and considerably more beneficial in terms of selectivity) to excite the atoms by a one-step excitation using far-UV light, which in turn depends on the energy deficit to the ionization limit of the upper laser-connected level, and that a substantial degree of ionization can be obtained when the interaction time is equal to, or larger than, the inverse of this effective collision rate.

Although the ionization limit of various elements differs, we can conclude that most elements have an ionization limit that is around 50 000–70 000 cm$^{-1}$ above the ground state (with an important exception for the alkali elements). Typical UV light (with 250–330 nm wavelength) excites ground-state atoms to states with energies around 30 000–40 000 cm$^{-1}$. This implies that the energy deficit of atoms excited by UV light often is in the 20 000–30 000 cm$^{-1}$ region (i.e. a few electronvolts). It is reasonable to assume that the effective collisional ionization rate is in the $10^4–10^5$ s$^{-1}$ range for states a couple of (or a few) electronvolts below the ionization limit. Because $n_2$ is close to unity for a saturated transition (on an orders of magnitude basis) and a typical laser illumination time is 10 ns, we get an ionization yield of about $10^{-4}–10^{-3}$ for a typical one-step LEI excitation. This shows that it is not possible in general to reach any high degrees of ionization from one-step LEI.
by light from two simultaneously pumped tunable lasers, alternatively referred to as stepwise excitation or two-step excitation (although also a rich variety of more complex denotations exists in the literature). (91)

### 3.4 Three-level Atoms Exposed to Two Laser Fields

There are several treatments of two-step (or even multistep) excitation of atoms in the literature, some of them with slightly different approaches. (73,74,92–94) Although the presence of metastable states might require a more sophisticated description and solution than those given here, we will describe two-step excitations of atoms in the simplest possible manner that can still correctly account for ionization depletion. This implies that we will only consider direct two-step excitations (i.e. those that share a common intermediate level), neglect the influence of metastable trapping levels, and solve the system of rate equations solely under steady-state conditions. The reader is referred to the literature for analyses of other configurations. (94)

#### 3.4.1 General Description of a Three-level System Exposed to Two Laser Fields

Consider a situation in which the atoms are described as three-level atoms (with levels denoted 1, 2 and 3 as shown in Figure 5) between which two resonantly tuned laser fields are acting. In line with the discussion above, it is often a good approximation to assume that the laser fields are acting. In line with the discussion above, shown in Figure 5) between which two resonantly tuned configurations.

#### 3.4.1.1 Rate Equation System for a Three-level System Exposed to Two Laser Fields

The rate equations for a three-level system exposed to two resonant laser fields, as depicted in Figure 5, can in general be written as in

\[
\frac{dn_1}{dt} = R_{13}n_1 + (R_{23} + B_{23}I^3_v)n_3 - (R_{31} + R_{32} + B_{32}I^3_v)n_3
\]

\[
\frac{dn_2}{dt} = (R_{12} + B_{12}I^{12}_v)n_1 - (B_{21}I^{12}_v + R_{21} + B_{23}I^3_v + R_{23})n_2 + (R_{32} + B_{32}I^3_v)n_3
\]

\[
n_{\text{atom}} = n_1 + n_2 + n_3
\]

#### 3.4.1.2 Solution of the Rate Equation System for a Three-level System Exposed to Two Laser Fields

Because ionization rates most often are considerably smaller than typical de-excitation and laser-induced rates, this three-level system can be solved under steady-state conditions. Under the assumption that smaller exciting collisions can be neglected in comparison with large de-exciting collision rates or laser-induced rates, the fraction of neutral atoms in the uppermost laser-connected state (level 3) can be written according to Equation (54):

\[
n_3 = \frac{B_{12}I^{12}_vB_{23}I^3_v}{(B_{12}I^{12}_v+a)(B_{23}I^3_v+b)+c}
\]

where the various coefficients are given in Table 2.

#### 3.4.2 Two-step Excitation Laser-enhanced Ionization

As long as there is any appreciable laser illumination on the upper transition, the main contribution to the ionization rate will be from the uppermost laser-connected level. Hence, for a two-step excitation, we can write the ionization rate as shown in Equation (55):

\[
n_{\text{ion}}(t) = k_{\text{eff}}^{\text{ion}}n_3(t)
\]

This implies that the ionization yield for a two-step excitation, \( N_{\text{ion}}^{\text{ion}}(t) \), can be written in an analogous way

to that for a one-step excitation, namely according to Equation (56):
\[
\overline{N}_{\text{ion}}^{\text{ns}}(t) = 1 - \exp(-k_{3,\text{ion}}^{\text{eff}}\tilde{t}_3 t)
\] (56)

Because the second excitation step often can excite the atoms to states a couple of electronvolts closer to the ionization continuum than can be achieved with one-step excitation (a second-step photon with a wavelength of 500 nm corresponds to a decreased energy deficit of 2.5 eV), the (effective) ionization rate can be increased by two to three orders of magnitude by using two-step excitation. In addition, because the fraction of neutral atoms in the uppermost laser-connected state can still take values close to unity under saturated conditions, this implies that the ionization yield can approach unity during the time of a laser pulse excitation. Two-step excitation is therefore the most efficient means to achieve strong LEI signals. As will be discussed below, two-step excitation not only increases the sensitivity but also improves the selectivity.

3.4.3 Two-step Excitation Laser-induced Fluorescence

Although one-step excitation often gives rise to a sufficiently high sensitivity (number of photons produced per atom) for the fluorescence technique, there are situations when a one-step excitation is not appropriate. One such example is when the atomic structure is such that resonance fluorescence is the only possibility when the atom is excited by light from one laser (as is the case for Cd, for example). Another example is when the fluorescence appears in the visible part of the region, a part of the spectrum in which substantial amounts of background emission often exist (e.g. from the blackbody radiation in ETAs). In this case the technique will not reach its optimum performance. A remedy for these situations is to use two-step excitation also for the LIF technique. (41,63) Because the fluorescence from a two-step excitation often appears in the UV or far-UV regions (thus, far from the exciting wavelengths, as well as blackbody radiation from the atomizer), two-step excitation LIF used to be characterized by freedom from scattered laser light and background radiation (see below). (72,94)

The expressions above (Equation 54 and Table 2) show that a strong fluorescence signal is expected from the upper laser-connected state (or from any collisionally coupled excited state) directly following the onset of laser excitation. However, as is shown by Equations (55) and (56), the atomic system can also suffer from an appreciable ionization depletion during the laser pulse if the uppermost laser-connected level has too small an energy deficit compared to the ionization limit. Taking this drain of the number of neutral atoms during the laser pulse into account, the rate of emission of fluorescence photons per atom (in this case, from the uppermost laser-connected level to any lower-lying level, here denoted i) can be expressed as shown in Equation (57):
\[
\overline{N}_{\text{ph}}(t) = A_{3i}\tilde{n}_3 t \exp(-k_{3,\text{ion}}^{\text{eff}}\tilde{t}_3 t)
\] (57)

This shows that the emission rate of fluorescence photons is highest directly following the onset of laser illumination, after which it decays with a decay time given by the inverse of the product of the effective ionization rate and the fraction of atoms in the uppermost excited level. This behavior resembles that for the LIF signal from a three-level system with a metastable state exposed to one laser field (Equation 37). This is not unexpected because the drain to ionization acts in an equivalent manner to that to a metastable state on these timescales.

Using Equation (2), the total number of photons emitted per atom from such a system (in a time t) can then be expressed as shown in Equation (58):
\[
\overline{N}_{\text{ph}}(t) = A_{3i}\tilde{n}_3 t [1 - \exp(-k_{3,\text{ion}}^{\text{eff}}\tilde{t}_3 t)]
\] (58)

This shows that for laser excitation to states whose (effective) collisional ionization rate is smaller than the inverse of the laser pulse illumination time (i.e. \(k_{3,\text{ion}}^{\text{eff}} < t^{-1}\)), the number of photons emitted per atom is approximately given by Equation (59):
\[
\overline{N}_{\text{ph}}(t) = A_{3i}\tilde{n}_3 t
\] (59)

which is equivalent to neglecting ionization depletion during the laser excitation.

If the excitation is performed to a state whose (effective) collisional ionization rate is significantly larger than the inverse of the laser pulse illumination (i.e. \(k_{3,\text{ion}}^{\text{eff}} \gg t^{-1}\)), the number of photons emitted per atom cannot exceed that shown in Equation (60):
\[
\overline{N}_{\text{ph}}(t \gg (k_{3,\text{ion}}^{\text{eff}})^{-1}) = A_{3i} \frac{k_{3,\text{ion}}^{\text{eff}}}{k_{3,\text{ion}}^{\text{eff}}}
\] (60)

due to ionization losses, which again is a similar behavior to that of the metastable three-level system exposed to one laser field (Equation 42). This shows that if the upper laser-connected level experiences too large an effective ionization rate, ionization losses can put a limitation on the number of photons emitted per atom from two-step excitation.

3.4.4 Fluorescence Dip

If the system of rate equations for a three-level system exposed to two laser fields (sharing a common intermediate level; Equations 51–53) is solved for the population
of the intermediate state, one can see clearly that this population (and hence the fluorescence from the intermediate state) will experience a decrease with the onset of the second-step laser.\(^\text{(64,98)}\) This phenomenon, which is similar to the ionization depletion phenomenon discussed above, has been termed fluorescence dip and has been proposed to have extraordinary diagnostic capabilities, e.g. for the determination of transition probabilities between excited states or photoionization cross-sections.\(^\text{(97)}\) The first investigations of the fluorescence dip phenomenon were made by Omenetto et al.\(^\text{(97,98)}\)

The relative decrease of the fluorescence from the intermediate state is termed relative fluorescence dip, \(\xi_2\). It was concluded that the maximum relative fluorescence dip for an optically saturated two-level system (such as that depicted in Figure 5) under steady-state conditions (i.e. neglecting the influence of ionization depletion) can be written as shown in Equation (61):

\[
\xi_2 = \frac{\tilde{r}_2[I_2^{(2)} - (I_2^{(2)})_{\text{sat}}, I_2^{(3)} = 0]}{\tilde{r}_2[I_2^{(2)} - (I_2^{(2)})_{\text{sat}}, I_2^{(3)} = 0] - \tilde{r}_2(I_2^{(2)} > (I_2^{(2)})_{\text{sat}}, I_2^{(3)} > (I_2^{(3)})_{\text{sat}})}
\]

For the case of Sr (with a 5s\(^2\)–5s 5p–5s 6d excitation, an upper state about 6000 cm\(^{-1}\) below the ionization limit, and degeneracy factors of 1, 3 and 5 for the three states, respectively), the optically saturated relative fluorescence dip should be 55% under the assumption that a steady-state situation prevails. It was found experimentally by Axner et al., however, that significantly larger optically saturated relative fluorescence dips could be obtained in an acetylene–air flame (up to 85%).\(^\text{(99)}\) Simultaneous measurement of the fluorescence dip and the increase in the ionization signal, coupled to an analysis based upon time-dependent rate equations for the fluorescence dip, revealed that the system was exposed to significant ionization depletion during the laser illumination time. This finding does not only show that substantial depletion of the intermediate laser-connected level follows the onset of the second excitation step, but it is also an example of the importance of taking ionization depletion into account when excitations of atomic systems to high-lying states in high-collision media are considered. This is in line with the theoretical predictions of ionization and fluorescence depletion made by Omenetto et al.\(^\text{(100)}\)

### 3.5 Conclusions – Justification of the Use of the Rate Equation Formalism

Section 3 has given the basic mechanisms for the production of fluorescence photons and charges (ions and electrons) primarily for the LIF and the LEI techniques, respectively, for both one- and two-step excitations in high-collision media. The description was given in terms of the number of photons emitted per atom in time \(t\), \(N_{\text{ph}}(t)\), and the fraction of analyte species that ionizes as a consequence of the laser illumination, \(N_{\text{ion}}(t)\), commonly also termed the ionization yield. It has been shown that both of these entities can reach values close to unity under a rather broad range of optimized pulsed conditions.

The description above was given in the rate equation formalism with no particular justification of its applicability. A correct representation of the excitation and de-excitation processes of atoms by narrow-band laser light can normally only be accomplished by using the so-called density matrix formalism.\(^\text{(101–103)}\) In this formalism, the atomic system is described by its quantum mechanical wavefunction. Solved with its full temporal dependence, the density matrix formalism is capable of describing both the time dependence of the dipole moments as well as the atomic level populations. The density matrix formalism is therefore able to describe effects that appear as a result of coherence between the induced dipole moments and the populations, e.g. rapid population oscillations between various states, commonly termed Rabi oscillations. Solved under steady-state conditions for the dipole moments, the density matrix equations (often termed Bloch equations in this context) revert to pure population equations of similar type to those of the rate equation formalism. These population equations are able to describe how an atomic system responds to narrow-band laser light of an arbitrary wavelength (i.e. including wing excitations) and can therefore predict, among other things, profile shapes of atomic transitions. They can also describe coherent contributions in the excitation process, e.g. two-photon excitations and dynamic Stark effects, such as broadening, splitting, and shifts of transitions induced by the laser light.\(^\text{(102–109)}\)

The density-matrix-based population equations, in turn, revert to the rate equations for sufficiently large laser bandwidths and collisional rates in the system (rather rapidly for one-step excitations but more reluctantly for two-step excitations).\(^\text{(73,103,107–109)}\) The rate equation formalism assumes, among other things, that there is a constant irradiance of the light across the width of the transition. This implies, in turn, that the formalism assumes tacitly that the light is fully in resonance with the transition. It is therefore unable to predict excitation profiles correctly. The high collisional rates in atmospheric pressure atomizers, together with the fact that light with bandwidths larger than that of the analytes is used, often justify (although not always) the use of the simpler rate equations for calculations of various-level populations.\(^\text{(73,103,107)}\) It has been commonplace, however, to use the rate equation formalism for description of excitation processes in more or less all fields of analytical spectrometry, even under situations...
when not all of the requirements for its use are fully fulfilled. The most common justification of the use of the rate equation formalism seems too often to be its simplicity rather than its appropriateness. As a result, the main part of the theoretical description in the literature of the interactions between laser light and atoms for analytical applications (as well as the description given above) has been cast in the framework of the rate equation formalism.\(^{35,59–63,71–74,94,99,103,110–112}\) One exception to this is the work by Boudreau et al.\(^{113}\) These authors have developed a user-friendly program, based upon a fully time-dependent density matrix model that describes stepwise excitations of atoms with degenerate states and collision-dominated conditions,\(^{108}\) that can predict phenomena such as dynamic Stark effects (splitting shifting and broadening) and two-photon transitions.\(^{113}\) The reader is referred to the literature for a proper description of how density matrix formalism is adapted to the conditions applicable to analytical spectrometry.\(^{103–109,114,115}\)

4 LASER-INDUCED FLUORESCENCE SPECTROMETRY

4.1 Introduction

LIF spectrometry, commonly also termed LEAFS when applied to analytical spectrometry, is based upon resonant absorption of laser radiation by the analyte and detection of the subsequently emitted fluorescence radiation.

Because laser light has a high spectral irradiance, the population of excited analytes can be made significantly larger when laser light is being used for excitation than when other light sources are used. This implies a high sensitivity and low detection limits for laser-based spectroscopic techniques in general and for LIF/LEAFS in particular. LOD in the low picogram per milliliter range, and in the femtogram range, have been obtained for a number of elements when used with a GF as atomizer. The technique has also been applied to other atomizers (e.g. flames and plasmas) but not with the same impressive LOD. In addition, because laser light consists of narrow bands, laser-based spectroscopic techniques generally have good selectivity. Because the LIF/LEAFS technique often uses a dispersive element for detection of the fluorescence (most often a spectrometer), the elemental selectivity is excellent. The LIF/LEAFS technique also has a large dynamic range (often five to seven orders of magnitude).

The first time fluorescence was used for analytical purposes was in 1964 by Winefordner et al.\(^{116,117}\) The first laser-based instrumentation for fluorescence was constructed by Fraser and Winefordner in 1971 and 1972.\(^{118,119}\) The first time frequency-doubling was used to extend the applicability of laser-based spectroscopic techniques for analytical applications was in 1973 when Kuhl and Spitschan detected Mg, Ni, and Pb in a flame by the LIF/LEAFS technique.\(^{120}\) Since then, a large number of papers have been published in the field, with significant contributions by the groups of Winefordner, Omenetto and Michel as well as others.

The range of elements that can be detected conveniently by the LIF/LEAFS technique has been restricted mostly to metals, although a few nonmetal elements also have been studied. In addition, the fluorescence technique has been used for the detection of molecules; it is then referred to as LEMOFS\(^{38}\) or occasionally LEMFS\(^{121}\). Moreover, in hot plasmas, where the degree of ionization is fairly high, ionic fluorescence has been used as an alternative to atomic fluorescence in order to improve the sensitivity or extend the number of accessible elements. The isotope selectivity of the LIF/LEAFS technique, on the other hand, is in general not very impressive under normal conditions because most optical isotope shifts are smaller than typical laser bandwidths or Doppler and collisional broadening mechanisms in most atomizers (although a few exceptions exist, e.g. among the actinides and lanthanides\(^{122}\)). Pulsed laser systems (primarily those with pulse duration in the nanosecond range, i.e. excimer-pumped dye laser systems and, to some extent, Nd:YAG-pumped dye laser or OPO systems) have shown the highest applicability for the LIF/LEAFS technique, although some impressive works also have been done with continuous-wave diode lasers. In addition, a variety of excitation–detection schemes have been investigated. Although the most common excitation–detection scheme is one-step excitation followed by Stokes direct-line or stepwise detection (mainly due to its simplicity and high fluorescence yield), some elements require two-step excitation in order to obtain the most favorable conditions.

This implies that in order to characterize fully the LIF/LEAFS technique with respect to its properties and applicability to analytical spectrometry, one can thus envisage a huge number of possible combinations of laser, atomization and detection instrumentation, excitation and detection schemes, as well as detection procedures. This naturally leads to a large spread in performance capabilities. Numerous detection limits of the LIF/LEAFS technique for a variety of elements have therefore been published in the literature throughout the years. It is not possible to cite all individual contributions to the continuously ongoing development of the LIF/LEAFS technique in a presentation like this so we have chosen to present the specific analytical attributes and characteristics of the LIF/LEAFS technique (sensitivity, types of noise, LOD, background reduction techniques, LDR, etc.) by referring to only a selection of papers in the field.
LASER SPECTROMETRIC TECHNIQUES IN ANALYTICAL ATOMIC SPECTROMETRY

4.2 Previous Reviews

The field of conventional-source-excited atomic fluorescence spectrometry (i.e. not using laser light for excitation) has been reviewed in detail by Butcher et al. Smith et al. have made an extensive compilation of a variety of atomic fluorescence spectrometry results (up to 1989) arranged by elements. The field of laser-induced/excited fluorescence, i.e. LIF/LEAFS, has been reviewed by several authors. An early review (from 1978) that serves as a good introduction to the practical aspects and early applicability of the LIF/LEAFS technique is that of Winefordner. Contemporary reviews that are focused on the basic properties of the fluorescence technique are those of Omenetto and Winefordner. Another early landmark review paper is that of Butcher et al. Omenetto has written many interesting papers about various aspects of the LIF/LEAFS technique but of special importance is the work by Omenetto and Human in which many important issues for the analytical use of LEAFS in flames, furnaces and inductively coupled plasmas (ICPs) are discussed in detail (e.g. the influence of peak power, pulse duration, spectral bandwidth and repetition rate on the detectability, together with the choice of excitation line and the optical arrangement of the detection system). This paper also contains many “handy recipes” for the LIF/LEAFS technique. Sjöström has written a comprehensible review of LIF/LEAFS in ETAs and, together with Mauchien, has given a critical view of the entire field of laser-based spectrometric techniques for analytical spectrometry. Interesting reviews not only of LIF/LEAFS but also of other laser-based spectroscopic techniques have been given by Falk, as well as by Omenetto. The most recent review of the LIF/LEAFS technique is that by Hou et al. The group of Winefordner has presented a series of papers critically discussing the ultimate possibilities of laser-based techniques in general and LIF/LEAFS in particular for analytical spectrometry, as well as their possibilities to achieve SAD.

4.3 Instrumentation

4.3.1 Typical Set-up

A typical experimental set-up for LIF/LEAFS is shown in Figure 6. Laser light is directed into an atomizer in which the sample is atomized. The emitted fluorescence is collected by an optical system and directed into a spectrometer. The transmitted light is detected by a sensitive detector – most often a photomultiplier tube.
(PMT), whose signal is subsequently amplified, and infrequently an intensified charge-coupled device (ICCD). When pulsed lasers are employed, gated detection, most often synchronously triggered with light from the laser, needs to be used (accomplished by a boxcar integrator for the case of a PMT). The output signal from the boxcar integrator is finally fed into a computer for data storage and handling.

4.3.2 Atomizers

4.3.2.1 Flames The first LIF/LEAFS measurements for analytical purposes during the 1970s used flames as atomizers.\(^{35,36,70,71,86,118–120,136–147}\) The prime reasons were the suitability of flames for analysis of liquid samples, their simplicity and reliability, and the fact that they have a continuous mode of operation (and hence provide a continuously refreshing distribution of atoms). However, although LIF/LEAFS in flames was prophesied early on to be a technique with extraordinary detectability and selectivity,\(^{35}\) the actual detection limits turned out not to be as impressive as first anticipated.\(^{37,38,60,64–67,78,81,115,148–158}\) The main reason is that the flame itself is far from the ideal atomizer for the LIF/LEAFS technique. Flames give rise to a rather large amount of background radiation and act as a source of scattering of laser light, which reduces the detection limits (see discussion below). However, LIF/LEAFS has been found to be a useful tool for the diagnostics of flames.

4.3.2.2 Electrothermal Atomizers The ETA, mostly represented by the GF, has several advantages in comparison with flames. The one that affects sensitivity the most is that the vaporized atomic cloud is held more concentrated, which implies that the atomic residence time (and thereby the interaction time) is longer. Other advantages are that only microliter volumes of samples are needed and that staged heating in an inert atmosphere makes analysis of samples with high concentrations of concomitant elements possible. A specific advantage with the ETA for the LIF/LEAFS technique is that it provides a rather quiet environment with a minimum amount of background radiation. It was therefore found early on that the LIF/LEAFS technique had its largest potential for analytical spectrometry in combination with the ETA.\(^{37,66,77,79,80,85,121,130,132,156–158}\)

4.3.2.3 Other Atomizers The development of the ICP during the last decade has considerably facilitated the determination of trace elements in many types of matrices using conventional detection techniques. The most significant advantages with the ICP are that it provides an efficient atomization, excitation and ionization environment. It has therefore taken over the role of the flame as the workhorse for a large variety of analytical investigations in many laboratories. This has implied that the ICP has been of interest also for the community of laser spectroscopists. LIF/LEAFS has therefore been applied to various types of plasmas.\(^{37,60,66,94,122,125,228–230}\) In addition, other atomizers, e.g. discharges\(^{231–235}\) and cells\(^{178}\) have been of interest for analytical laser-based spectrometric techniques. The analytical performance of LIF/LEAFS systems containing these types of atomizers, however, has not been found to rival those of ETA systems. Therefore, only a limited number of studies in this area have been pursued.\(^{37,60,66,94,122,125,228–235}\)

4.3.3 Laser Sources

A variety of lasers have been used for the LIF/LEAFS technique over the years. Pulsed laser systems (primarily those with pulse duration in the nanosecond range, i.e. excimer-pumped dye laser systems,\(^{37,66,67,80,120,127,153,155–159,191–199}\) N\(_2\)-pumped dye laser systems,\(^{118–121,123,148,152,214–224}\) and Nd:YAG-pumped dye laser\(^{37,77,79,85,190,200–209}\) or OPO systems\(^{114,227,228}\) have shown the highest applicability for the LIF/LEAFS technique, although some impressive studies also have been done with Cu-vapor lasers,\(^{220–223}\) ion-pumped dye laser systems,\(^{142–145,151}\) flashlamp-pumped dye lasers\(^{146,147,149,150}\) and continuous-wave diode lasers.\(^{225}\)

The prime reasons for the success of pulsed lasers for LIF/LEAFS (as well as the ionization techniques, see below) are: versatility in producing UV light (because tunable UV laser light is normally produced by frequency-doubling visible light in a nonlinear crystal using processes that are strongly nonlinear, then, with a conversion efficiency that increases with irradiance, pulsed lasers, which have a significantly higher irradiance than continuous-wave systems, can more easily produce UV wavelengths); the possibility of producing a large signal over a short period of time (thereby maximizing the S/N ratio); and the fact that they can saturate the transitions more easily than continuous-wave systems.

A disadvantage with pulsed laser systems is that the duty cycle is rather poor, so that only a small fraction of all atoms entering the atomic reservoir will be exposed to laser light. Consider, for example, the case of a 10-Hz Nd:YAG laser illuminating an air–acetylene flame (whose rise time is around 10 ms\(^{–1}\) and width is around 1 cm). The analyte atoms are being distributed over an area of 100 cm\(^2\) in-between each laser firing. If the laser beam diameter is between 3 and 4 mm, it covers an area of about 10 mm\(^2\). Hence, not more than 10\(^{–9}\) of all the atoms in the flame can interact with the laser light. The situation improves if excimer-pumped laser systems are used.
Modern excimer lasers can produce laser pulses at repetition rates of up to a few hundred hertz (although often at a reduced pulse energy). An excimer-pumped dye laser system running at 100 Hz can then potentially still interact with only a few percent of all the atoms in the flame using an enlarged beam. This is, however, not such a devastating drawback for LIF/LEAFS as might be expected because the pulsed detection also reduces the noise in the system (noise is measured only over 2 µs s⁻¹ using a 100-Hz system and a 20-ns fluorescence detection gate).

Copper vapor lasers, on the other hand, which produce pulses at kilohertz repetition rates, can potentially interact with all atoms in a sample. However, a severe drawback of metal-vapor-pumped laser systems is that not the entire spectral region can be accessed.

The most commonly used type of laser for LIF/LEAFS is the XeCl excimer-pumped dye laser, mainly due to a combination of a high repetition rate (up to 500 Hz), a high peak power (typically up to 1 MW in the visible spectrum and tens of kilowatts in the UV range) and pulse durations that are a few times longer than those of Nd: YAG lasers. Another issue of importance in this respect is that there are commercial excimer-pumped dye laser systems in which the dye laser cuvette and dye pump form a combined unit that can be removed/exchanged rather easily. With access to a few sets of dye laser cuvette and pump units, a change of dye can be accomplished rather conveniently, i.e. within a few minutes (a procedure that often takes many hours with other dye laser systems).

The recent development of new pulsed tunable laser sources has had some impact on the field of analytical spectrometry. The development of OPO systems, with a rapidly scanned wide spectral tuning range (220–2200 nm) and pulse energies of tens of millijoules per pulse in the visible region and several millijoules in the UV region, takes the laser-based spectroscopic techniques one step further towards multi-element determinations. It is not clear, a priori, however, that pulsed dye laser systems with nanosecond pulse lengths provide the optimum excitation source for the LIF/LEAFS technique for all elements in all instances. As will be discussed further below, they can, under certain conditions, be rivaled by other types of laser systems (depending on the dominating type of noise).

The development of diode lasers has, in particular, opened up the possibility of constructing new, powerful and compact LIF/LEAFS instrumentation. Although most applications of diode lasers for analytical purposes so far have been pursued within the field of FM or WM absorption techniques (which is described in section 6), Zybin et al. established 10- and 20-fg LOD for Li and Rb in a graphite tube, respectively, detected by diode-laser-excited LIF/LEAFS.

4.3.4 Detection Equipment

4.3.4.1 Optical Systems

As was concluded by Yuzevovskiy et al. and clearly summarized by Hou et al., there are five main requirements for an efficient optical system, namely: a high light collection efficiency in both the UV and visible regions; a good ability to discriminate between background and analytical signals; minimal losses of the analytical signal at the detection wavelength; easy-to-align optics; and inexpensive and commercially available optical components.

The optical systems that have been used the most with the LIF/LEAFS technique over the years are the three that are depicted schematically in Figure 7 (exemplified using a graphite tube as the atomizer). Most early experimental set-ups directed the fluorescence into the spectrometer in a right-angle mode of detection, as displayed in Figure 7(a) (see references 35, 37, 65, 66, 77, 85, 115–121, 132, 137–153, 157–174, 203–208, 213–222). Later set-ups have instead had front-surface detection using a pierced mirror (see Figure 7(c)).
in the range of hundreds of megahertz to a few gigahertz, the duration of the emitted fluorescence will be of the same order of magnitude as the duration of the laser pulses (i.e. most often a few to some tens of nanoseconds). Furthermore, because these types of laser have repetition rates of some tens or hundreds of hertz, the duty cycle is low (typically $10^{-6} - 10^{-5}$). Gated detection therefore has to be used in order to obtain the optimum S/N conditions.

By far the most common detector used is the PMT,\cite{37,65,66,77,79,116 - 121,132,137 - 150,152 - 182,190 - 224,227} because it has a number of useful properties: it is sensitive, inexpensive and easy to use. The only disadvantage with a PMT is that it is not capable of providing any fluorescence spectrum – it can only give rise to one data point per laser firing (corresponding to the fluorescence integrated over the bandpass of the spectrometer at the center wavelength chosen). When PMTs are used the gating is done by a boxcar integrator, whereas diode arrays and charge-coupled device (CCD) detectors, which sometimes have been used with the LIF/LEAFS technique, need to be equipped with an intensifier in order to provide the necessary gating.

ICCD detectors\cite{80,185 – 190} or diode arrays\cite{151,226} have the capability of detecting an entire fluorescence spectrum for each laser shot, which can be an advantage when samples with complex matrices are to be detected. One example of the versatility of an ICCD detector is shown in Figure 8. The figure shows a pair of fluorescence spectra from Ti atoms excited by pulsed 264.108-nm light in a GF. Figure 8(a) displays the situation in a normal Ar atmosphere whereas Figure 8(b) shows the corresponding spectrum when Ar was substituted by N$_2$.\cite{80} As can be concluded from the figure, the fluorescence spectrum is fairly rich. To aid in the identification of the fluorescence peaks, however, Ar was occasionally substituted for N$_2$, which is a better quencher of excited atoms. The peaks that decrease the most (labeled 1–11 in Figure 8) originate from “indirect” transitions (i.e. originating from upper levels that are different from that accessed by the laser), whereas the others refer to “direct” transitions (i.e. those that originate from the upper laser-connected level). This study led to the conclusion that most of the fluorescence spectra from Ti are dominated by “indirect” transitions. In addition, many direct transitions were found to be inferior to other indirect transitions, making it virtually impossible even to make a qualified guess of the optimum excitation–detection combination prior to the experiment. The results indicate also that the collisional redistribution processes amongst the excited levels are, in general, faster than typical fluorescence rates for Ti in GFs (which supports the discussion about rapid collisional redistribution processes among excited states in section 3.3.1.1 above).
Laser Spectrometric Techniques in Analytical Atomic Spectrometry

Figure 8 Two LIF/LEAFS/ICCD spectra from Ti atomized in a GF excited by 264.108-nm light to the 3d2 4s 4p3D1 state at 37,852.021 cm⁻¹ when Ar (a) and N₂ (b) have been used as buffer gas. A full identification of the fluorescence lines is given in Ljung et al. N₂ is a stronger quencher than Ar, so peaks 12 and 13 can be referred to as “direct” transitions. Note that several of the indirect peaks are equally as strong as the direct ones in the Ar atmosphere. (Reproduced from P. Ljung, E. Nyström, J. Enger, P. Ljungberg, O. Axner, Spectrochimica Acta, 52B, 675–701, Copyright 1997, with permission from Elsevier Science.)

Figure 9 The most commonly used excitation–detection schemes for the LIF/LEAFS technique. Thick and thin arrows represent laser excitations and fluorescence, respectively. (a) Resonance fluorescence (R₁₂F₂₁); (b) Stokes direct line fluorescence (R₁₅F₁₂); (c) Stokes step-wise line fluorescence (R₁₃F₁₁); (d) connected double-resonance stepwise line fluorescence (R₁₂R₂₄F₃₁); (e) disconnected double-resonance direct line fluorescence (R₁₄R₃₅F₅₂). Both conventional notation and the new IUPAC terminology (within parentheses) are used.

4.3.5 Types of Fluorescence Transitions

A variety of different excitation–detection modes have been used throughout the years, mainly dictated by the atomic structure of the analyte to be investigated. Although attempts have been made to define a clear nomenclature for these various excitation–detection modes, a slight disorder has been prevalent. Lately, however, a new International Union of Pure and Applied Chemistry (IUPAC) notation for the description of various excitation–detection processes, applicable to fluorescence as well as ionization techniques, has been released. A few of the most commonly used excitation–detection schemes for the LIF/LEAFS technique are given in Figure 9. The reader is referred to the literature, e.g. any of the works by Omenetto and Winefordner, for a more extensive description of possible excitation–detection schemes for the LIF/LEAFS technique.

4.4 Analytical Performance

The detectability of a certain species in a given atomizer depends on a number of factors. On the one hand, we have the sensitivity, i.e. the relation between the measured signal and the concentration (or amount) of the analyte in the sample. On the other hand, there is always noise in the system. The relation between the two determines the LOD for the system. Because both the sensitivity and limiting noise will differ between various types of instrumentation, the LOD for a given element will depend on the particular atomizer and laser system used, as well as their mode of operation.

4.4.1 Sensitivity

The sensitivity for a given instrumentation is normally defined as the rate of change of the signal with amount/concentration of analyte. Because PMTs are often capable of detecting single events and LIF/LEAFS measurements very seldom are limited by detector noise...
(see below), it is often more convenient to define an overall efficiency of a system: as the number of events detected per concentration unit of the analyte in the sample for continuous-mode atomizers; and as the number of events detected per mass unit of the analyte or per atom in the atomizer for discontinuous atomizers (furnaces, discharges etc.). There are, however, several closely related entities defined and discussed in the literature (e.g. the efficiency of detection and efficiency of measurement).\(^{37,65,129,174,214,243,244}\) The detection efficiency, for example, introduced by Alkemade,\(^{243,244}\) refers to the probability that a given atom appearing in the probed volume produces an event during the probing time. However, we will not scrutinize these issues in detail here. It is sufficient to conclude that the overall sensitivity can be written as a product of several individual efficiency terms, e.g. the sample introduction efficiency, the atomization efficiency, the illumination efficiency (the fraction of atomized atoms that is illuminated by the laser light), the number of photons emitted per atom (as defined in section 3), the solid angle over which fluorescence is collected, the light collection efficiency of the optical system, the transmission of the spectrometer, and the quantum efficiency of the detector.\(^{37,129,174,243,244}\)

One illustrative example of the concept of sensitivity is the determination by Wei et al.\(^{174}\) of the overall efficiency for detection of Pb atoms in an ETA by the LIF/LEAFS technique for three different experimental set-ups: right-angle detection combined with dispersive detection; front-surface detection combined with dispersive detection; and front-surface detection combined with nondispersive detection.\(^{174}\) These authors found overall efficiencies for their three set-ups of \(4.3 \times 10^{-7}, 2.0 \times 10^{-6}\) and \(1.2 \times 10^{-5}\), respectively. The major reason for the relatively low numbers for the overall efficiency is the small solid angle over which fluorescence is collected by the detection system. Their results show that although front-surface detection has a higher overall efficiency than right-angle detection, nondispersive detection systems can, in turn, have a higher overall efficiency than dispersive detection.

4.4.2 Noise and Background Signals

Noise in a measurement can be classified as either extrinsic or intrinsic. Extrinsic noise is the noise that arises from a nonspecific background signal that is present even in the absence of analyte. Extrinsic sources of noise comprise, for example, thermal noise, background emission, stray light and concomitant scatter. The intrinsic noise, on the other hand, is due to the inherent statistical fluctuations in the number of atoms present in the volume probed by the laser.\(^{35,132,244}\) Under the most favorable conditions, only the intrinsic noise will limit the detectability of a certain species. Although discussed in the literature in the assessment of the ultimate detection power of laser-based techniques (in particular, in connection with the concept of SAD)\(^{54,129,243,244}\) and because of the existence of many other types of noise (see below), the intrinsic noise will only occasionally limit an actual measurement under real conditions.

4.4.2.1 Thermal Noise

Thermal noise consists of electronic noise from the instrumentation, e.g. detector noise and preamplifier noise, and is an omnipresent source of noise that only occasionally (when a small number of events is to be detected) is the limiting factor for the LIF/LEAFS technique. Because PMTs can detect a single event above its noise level, a low number of signal photons more often creates a situation limited by the intrinsic noise than by the thermal noise in experiments in which very few background photons are created. Hence, it is the consensus that PMT-based systems are seldom limited by the thermal noise.

A gated CCD detector (i.e. an ICCD), on the other hand, which consists of many thousands of individual detector elements each with its own noise, can, when used in a binned or integrating mode (as is most often the case when hooked up to a spectrometer), give rise to a higher amount of detector noise. Hence, although not yet fully confirmed, especially regarding the most modern ICCD systems, it seems most plausible that the detection of weak signals using ICCDs in binned modes can be limited by the thermal noise from the detector rather than the intrinsic noise.\(^{187}\)

4.4.2.2 High-frequency (Radio-) Interferences

High-power pulsed laser systems can produce significant amounts of high-frequency (radio-) interferences that can interfere with the detection equipment. Although this type of noise is more of a nuisance for the LEI technique (in which minuscule signal currents are measured in unshielded environments), it will only occasionally limit the detectability for the LIF/LEAFS technique (especially when laser or detector systems are used that are not fully shielded electrically).

4.4.2.3 Nonlaser-induced Background Signals

Nonlaser-induced background signals from the atomizer comprise emission from constituents in the atomizer or blackbody radiation. Although flame emission can be significant at the wavelength regions where the most frequent flame species emit (e.g. OH and C\(_2\)), the general trend is that the atomizer background signals decrease with wavelength.\(^{38}\) For ETAs, the nonlaser-induced background signals consist mostly of the blackbody radiation, which can limit the detectability primarily at wavelengths above 300 nm.\(^{130}\) A remedy for this is thus
to strive to obtain detection wavelengths as far as possible into the UV region.\(^{(176)}\)

### 4.4.2.4 Stray Light

Stray light is defined as laser light reflected into the detection system from various parts of the instrumentation (but excluding scattering from the sample). Most of the stray light originates from scattering from various optical surfaces. This source of noise is therefore most severe when closed atomizers (e.g. a GF) are used (in which the light has to pass through a window before it enters the interaction volume). Various attempts to design the instrumentation (i.e. the atomizer\(^{(132,137,164)}\) or the optical system\(^{(239,240)}\)) so that light originating from the entrance and exit windows does not reach the detector have therefore been made. One possibility is to use an optical system with a short depth-of-focus and the atomizer with its windows at the Brewster angle as far from the interaction region as possible. This implies that only a small part of the stray light will be imaged onto the spectrometer slit.

Stray light is always the dominating source of noise for resonant LIF/LEAFS but can also affect the measurements when other types of excitation–detection modes are used (especially when the detection wavelength is close to the excitation wavelength).\(^{(144,149,159,176,207,214,245)}\)

Remedies for this are to use excitation–detection wavelengths that are as widely separated as possible and to use a double monochromator (which has a better stray-light rejection ratio than ordinary monochromators/spectrometers).\(^{(200)}\) However, these measures are insufficient if the stray light originates from ASE from the laser (which is a broad emission background from dye lasers that appears in addition to the stimulated light that is produced in the system) or if it originates from so-called “environmental” (or “white”) fluorescence. Environmental fluorescence arises when UV light impinges upon optical components that generate fluorescence photons in the 290–420 nm region.\(^{(209)}\)

An efficient solution to this problem is to use double-resonance fluorescence (as was shown in Figures 9d and 9e), because the fluorescence light then can have a significantly shorter wavelength than the excitation light (described in more detail below).\(^{(94,376)}\) The ordinary spectrometer instrument can then be complemented with either a suitable filter (which thus only transmits the fluorescence wavelength and not the laser excitation wavelengths) or with a solar-blind photomultiplier (which is sensitive only to UV light).\(^{(72,176)}\)

### 4.4.2.5 Concomitant Scatter

Scattering of laser radiation off particles introduced by the sample is referred to as concomitant scatter.\(^{(245)}\) This phenomenon is closely related to the concept of molecular fluorescence, which may be generated either by the species commonly present in the atomizer (e.g. OH, NO, or \(\text{C}_2\) molecules in flames) or by those being produced by the sample (metal chlorides, metal oxides or metal hydroxides).\(^{(38,139–141,145,246,247)}\) These types of background can therefore be significant (and severely limit the detectability) when samples containing large amounts of nonvolatile and undissociated matrices are detected. Concomitant scatter is generally more severe in flames than in ETAs because the flame, with its chemical environment, has a larger tendency to produce nonvolatile species than has an inert gas atmosphere.\(^{(38)}\)

Atomizers with large temperature gradients (e.g. graphite filaments or rods) also give rise to potentially larger concomitant scatter and molecular fluorescence than those with good temperature homogeneity (e.g. transversely heated graphite atomizers), because the cooler region may allow recombination of matrix elements or the formation of scattering species from the analyte.\(^{(38,208)}\)

One of the very few documented examples of the existence of concomitant scatter in a GF is shown in Figure 10 in which Sb is detected in riverine and estuarine water by LIF/LEAFS in a GF using an ICCD detector.\(^{(189)}\)

Figure 10(a) shows fluorescence spectra from (tenfold-diluted) estuarine water (containing 540 pg mL\(^{-1}\) Sb and \(2 \times 10^7\) times more Na, i.e. 11 600 \(\mu\)g mL\(^{-1}\)) for three different laser wavelengths (in resonance with the Sb transition as curve A, and detuned –30 and +30 pm as curves B and C, respectively). The peak in curve A at around 289 nm, marked with an arrow in the figure, originates from Sb, whereas the other regularly spaced peaks in Figure 10(a) belong to some unidentified molecular species in the sample. Figure 10(b), in which riverine water (containing 275 pg mL\(^{-1}\) Sb and about \(10^4\) times less Na, i.e. 1.86 \(\mu\)g mL\(^{-1}\)) is investigated, shows no such background, indicating that it originates from the matrix in the estuarine water. Despite the clearly visible background signal from the matrix in the estuarine water at this particular excitation wavelength, the most prevalent situation for the LIF/LEAFS technique is the situation shown in Figure 10(b), i.e. in which there is no matrix background signal.

### 4.4.2.6 Nonanalyte Atomic Fluorescence

Nonanalyte atomic background fluorescence is a rather uncommon phenomenon for the LIF/LEAF technique in ETAs (although it exists to a certain degree in flames owing to their richer chemical composition).\(^{(140)}\) The main reason for this is the inherent double selectivity of the LIF/LEAFS technique. A potentially interfering species needs to have a wavelength overlap in both the excitation and detection steps in order to interfere with the analyte signal. Because atoms generally have very narrow excitation profiles, background signals from...
nonanalyte atoms are extremely rare, although molecular background signals occasionally have been found (as was exemplified in Figure 10).

4.4.2.7 Conclusions  It can be concluded that the laser stray light (e.g. “environmental” fluorescence), atomizer emission, or concomitant scatter limits the detectability of LIF/LEAFS in most practical situations.

4.4.3 Means to Reduce Background Signals
In order to reduce the influence of background signals, a variety of background-reducing or background-correction techniques have been developed and investigated.

4.4.3.1 Double-resonance Fluorescence  As was concluded above, the limiting noise in many situations

---

**Figure 10** Two LIF/LEAFS/GF fluorescence spectra from tenfold-diluted estuarine water (a) and riverine water (b), respectively. The laser wavelength is 231.147 nm, which is fully resonant with the $5p^33^4S_3^2-5p^26s^4P_{1/2}$ transition in Sb for the two curves A. Curves B and C correspond to detuned laser excitation (−30 and +30 pm, respectively). The Sb contents in the two samples were assessed to be $0.275 \pm 0.01$ and $0.54 \pm 0.07$ ng mL$^{-1}$, whereas the Na contents were 1.86 and 11 600 µg mL$^{-1}$, respectively. The peak in curve A at around 289 nm originates from Sb, whereas the other regularly spaced peaks in (a) belong to some unidentified molecular species in the estuarine sample. (Reproduced by permission of the Royal Society of Chemistry from J. Enger, A. Marunkov, N. Chekalin, O. Axner, *Journal of Analytical Atomic Spectrometry*, 10, 539–549 (1995).)
is laser stray light, concomitant scattering or atomizer background emission noise (e.g. blackbody radiation in furnaces). A possible approach to decrease the influence of atomizer background emission noise is to bring the fluorescence far into the UV region. This often requires laser photons of very short wavelength (sometimes even below 220 nm), which can be difficult or cumbersome to produce. An alternative approach, which can reduce the influence of all these sources of noise significantly, is to use a double-resonance (two-step) excitation (i.e. to excite the atoms simultaneously with two laser pulses), as was shown in Figure 9(d) and (e). The greatest advantage of double-resonance excitation is that the fluorescence light can have a significantly shorter wavelength than the excitation light.\(^{72,94,176}\)

Vera et al.\(^{79}\) defined the ideal excitation–detection conditions, as shown in Equation (62):

\[
\begin{align*}
\lambda_1, \lambda_2 &> 320 \text{ nm} \\
\lambda_F &< 320 \text{ nm}
\end{align*}
\]

where \(\lambda_1\) and \(\lambda_2\) are the two excitation wavelengths and \(\lambda_F\) is the wavelength at which the fluorescence is detected. This allows for the use of a solar-blind PMT (i.e. one that does not respond to light above 320 nm) and implies that the detector will respond neither to any laser stray light nor to any concomitant scatter. Double-resonance excitation has thus a greater potential to bring the LIF/LEAFS technique closer to the predicted intrinsic LOD than ordinary one-step excitation–detection schemes.

The first double-resonance excitation LIF/LEAFS measurement was made on Pb by Miziolek and Willis in 1981 under the name of saturated optical nonresonant-emission spectrometry (SONRES).\(^{77}\) Lead atoms were excited by 283.3- and 600.2-nm light. They concluded that very short wavelength photons (e.g. down to 202 nm) could be generated by collisional energy transfer among excited states. They studied a number of transitions and found the 261.4-nm transition to be the strongest. They quoted an order-of-magnitude LOD of 1 fg for Pb. Because this work was performed under an unconventional name, it took the community of scientists several years to realize the importance of this mode of detection for LIF/LEAFS. A number of two-step excitation LIF/LEAFS measurements were made in 1988 by Omenetto et al. (establishing LOD for Tl, Pb and Cd in a GF of 2.5 and 18 fg, respectively),\(^{176}\) by Leong et al. (who studied both direct and disconnected double-resonance excitations in Pb and made a comparison with one-step excitation),\(^{200}\) and in 1989 by Vera et al. (who assessed LOD for In, Ga and Yb of 2, 1, and 220 fg, respectively).\(^{79}\) Additional two-step excitation experiments have been performed by several authors thereafter, e.g. Sjöström et al. when detecting V,\(^{194}\) Axner and Rubinsztein-Dunlop when investigating Cr,\(^{177}\) and Petrucci et al. when detecting Au.\(^{158}\)

### 4.4.3.2 Multichannel Background Monitoring

Various approaches for the monitoring of background signals have been developed and scrutinized.

A multichannel background correction technique for pulsed LEAFS with a GF was developed by Sjöström (a poor man’s multichannel analyzer but with the benefit of using PMTs).\(^{120}\) The background was measured simultaneously with the analyte signal using three optical fibers positioned at the exit slit of the monochromator and coupled to two different PMTs (one for the center fiber and one for the two flanking fibers). Blackbody radiation, scattered laser light and molecular fluorescence could be corrected for by this simultaneous background-correction technique. Gallium was detected with an LOD of 50 fg.

An alternative approach was taken by Remy et al.\(^{201}\) They split the fluorescence light, using a beamsplitter, into two different monochromators – one tuned to the analytical transition and one slightly detuned so as to measure the background from scattered laser light, furnace emission, concomitant scatter, etc. The authors conclude that this leads to improvements in LOD and precision. The drawback is that the beamsplitter reduces the analytical signal by a factor of 2.

A more powerful approach to this concept is to use an ICCD to detect the fluorescence.\(^{80,186–189}\) An ICCD detector has several advantages over a PMT. It can detect several wavelengths simultaneously, so it can be used for fast and convenient investigations of the fluorescence spectra to find the most sensitive excitation–detection wavelength combination from atoms with complex atomic structure. It can be used to increase the absolute sensitivity of the LIF technique in a GF as compared to PMT detection by allowing simultaneous detection of the fluorescence at several wavelengths. It can monitor and correct for background signals from matrix interferences, blackbody radiation and scattered laser light both at and around the wavelength of detection, which is of special importance when samples with high concentrations of matrices are being analyzed. This leads to an improved spectral selectivity. In addition, owing to the delayed read-out of the ICCD detector (delayed in time with respect to the laser pulse), it has a high immunity from radiofrequency pick-ups emitted from the pump laser. Moreover, by storing a number of consecutive fluorescence spectra from within one furnace heating, the time development of spectra from the analyte as well as from any matrix constituent in the sample giving rise to background signals can be studied. Finally, a two-dimensional ICCD detector can be used for spatial studies of atomization and diffusion processes in the
GF if combined with an imaging spectrometer. There are a few disadvantages of ICCD detectors, the most significant of which are: they can have a lower sensitivity than a PMT, resulting from a lower quantum efficiency of the photocathode; and they have a limited read-out rate (around one or a fraction of a hertz for a full two-dimensional read-out, or up to a few hundred hertz for binned read-outs). They produce a huge amount of data, which necessitates the use of computers with large data-storage capabilities, and they are relatively expensive.

The first use of an ICCD together with LIF/LEAFS in an ETA was the investigation of Ni. The most sensitive and versatile excitation and detection wavelengths were identified. The LOD of Ni by LIF/LEAFS in an ETA could thereby be improved by two orders of magnitude. The ICCD detector was also compared with an ordinary PMT. The LOD were found to be 15 and 10 fg for ICCD and PMT detection, respectively. The simultaneous monitoring of entire fluorescence spectra by the use of an ICCD made possible the detection of Ni in various aqueous standard reference samples with sodium concentrations ranging from micrograms to tens of milligrams per milliliter (riverine water and estuarine water) with good accuracy and precision. ICCD detectors have also been used for studies of Ti (as was shown in Figure 8 above) and Sb in environmental samples and human blood.

4.4.3.3 Zeeman Background Correction Another technique for background correction is the Zeeman technique, extensively used for atomic absorption spectrometry (AAS) in an ETA. Use of the Zeeman background-correction technique together with LIF/LEAFS in an ETA (termed Zeeman electrothermal atomization/laser-excited atomic fluorescence spectrometry (ZETA/LEAFS)) has been studied by the group of Michel. ZETA/LEAFS was first investigated with Co as a pilot element by Dougherty et al. ZETA/LEAFS was found to correct for furnace blackbody radiation, scatter and stray light. However, the Zeeman effect has a drawback in that it degrades sensitivity. Dougherty et al. found an LOD of 0.3 pg with and 0.7 pg without Zeeman correction. It was later found that the Zeeman correction degraded the LOD for elements such as Ag, Co, In, Mn, Pb, and Tl by a factor between 1 and 10, whereas no successful Zeeman correction could be done for Cu. The Zeeman correction technique did not affect the LOD but enabled correction for scatter in resonance fluorescence determination of Mn in a zinc chloride matrix and brain tissue. A diagnostic study of the Zeeman effect was made by Preli et al. They investigated the influence of Zeeman splitting, applied field strength, laser excitation line width, and atomic spectral profile on the LOD and LDR for six elements (Ag, Co, Cu, In, Pb, Tl). All these investigations used a longitudinal Zeeman correction system. Transverse ZETA/LEAFS has been investigated by Irwin et al. on Pb and Co.

4.4.3.4 Wavelength-modulating Laser-induced Fluorescence/Laser-excited Atomic Fluorescence Spectrometry Techniques Various WM methodologies have been investigated for the LIF/LEAFS techniques by Goff et al. and by Su et al. The light from a dye laser was modulated periodically either by rapid tuning of an etalon or by tilting a mirror in the cavity by electrical means. Both of these groups reported on the reduction of the laser scatter background in various types of measurements. A potential drawback of this type of wavelength-jumping method is that it cannot correctly compensate for a structured background.

4.4.4 Limits of Detection LOD are normally defined as the concentration (or absolute amount) of analyte in a sample that produces a signal equivalent to three times the standard deviation of the noise associated with the blank. For steady-state atomizers (e.g. flames and plasmas) LOD are expressed in concentration units (e.g. ng mL$^{-1}$), whereas for nonsteady-state atomizers (e.g. ETAs and vapor cells) absolute amounts are used (e.g. pg). A convenient way to determine LOD for a given instrumentation is to divide the amount of noise (three times the standard deviation of the noise associated with the blank) by the sensitivity. This implies that LOD depend both on the sensitivity and the noise of the technique. Because both of these two entities in turn depend on most other parts of the instrumentation (type of laser, atomizer, detector, as well as sample constituents), LOD can vary widely between various elements and instrumentation. This also implies that one given instrumentation does not necessarily provide the optimum conditions for all elements. This can be exemplified by the works by Wei et al. and Vera et al.

Wei et al. determined the LOD for two elements (Tl and Pb) atomized in a GF for the three different optical systems examined for their overall efficiency above (i.e. right-angle detection combined with dispersive detection; front-surface detection combined with dispersive detection; and front-surface detection combined with nondispersive detection). They found that although the sensitivity increased with front-surface detection (in comparison with right-angle detection) for Tl (for dispersive detection), the noise increased by almost the same amount. Hence, the front-surface and the right-angle approaches gave the same LOD for Tl (3 fg). For Pb, on the other hand, the sensitivity increased significantly.
more than did the noise, and LOD were improved by almost one order of magnitude for front-surface detection (from 7 to 1 fg). They attributed this difference to the fact that the dominating source of noise for Pb was blackbody emission, whereas scattered laser light noise dominated for Tl. They therefore concluded that the front-surface mode of detection will offer a significant improvement of the LOD over right-angle mode detection for situations where blackbody emission dominates but not necessarily when noise from scattered laser light is dominating.

The same authors also found that nondispersive detection (e.g. narrow-bandpass filters) had an even better light-gathering power, and hence a better sensitivity, than dispersive detection (using a spectrometer). They therefore claimed that nondispersive detection should reduce noise and lead to improved LOD. It remains to be proven, however, whether nondispersive systems can be as versatile as dispersive systems because they generally have a lower selectivity.

Vera et al. evaluated three different laser systems (nitrogen-, copper-vapor- and Nd:YAG-pumped dye laser systems, respectively) for their Pb detection power by LIF/LEAFS in a graphite tube. They found that the best LOD of Pb could be achieved by the high-repetition-rate (6 kHz) Cu-vapor laser (0.5 fg, laser scatter limited), whereas a 20-Hz repetition-rate nitrogen gas and a Nd:YAG laser yielded virtually identical LOD (3 fg).

However, in an accompanying work by the same authors, concerned with the detection of Fe and Ga, the Cu-vapor laser did not yield the same advantage over the other systems. The reason was attributed to the low pulse energy of the Cu-vapor laser (a few hundred nanojoules per pulse), which did not allow for optical saturation of the transitions in these elements. LOD for Ga, for example, were found to be almost two orders of magnitude lower when detected by the Nd:YAG laser than with the Cu-vapor laser (25 versus 2000 fg). Despite the appealingly high repetition rate, Cu-vapor lasers have not been used extensively for LIF/LEAFS in an ETA, with the powerful exception of the direct determination of Pb in Great Lakes waters by Cheam et al.

The above examples show that it is not clear, a priori, that pulsed dye laser systems of nanosecond pulse length always provide the most optimum excitation source for the LIF/LEAFS. They can, under certain conditions, be rivaled by other types of laser systems. Theoretical considerations for (and discussions of) S/N ratios and LOD for the LIF/LEAFS technique have been given by a number of authors. The actual LOD for the LIF/LEAFS technique that have been achieved in various experiments are presented below (with respect to the type of atomizer used).

#### 4.4.4.1 Laser-induced Fluorescence/Laser-excited Atomic Fluorescence Spectrometry in Flames

Table 3 gives a compilation of the best LOD for the flame LIF/LEAFS technique. As was mentioned above, although the LIF/LEAFS technique was first applied to flames as atomizers and a large number of studies have been done in the field, the actual detection limits have turned out not to be as impressive as first anticipated. The assessment of sub-nanogram per milliliter detection limits of Pb and Tl in an acetylene–air flame (0.02 and 0.8 ng mL⁻¹, respectively) by Human et al. in 1984 is still among the most impressive results by flame LIF/LEAFS. Most other elements show detection limits in the ng mL⁻¹ range (ranging from some parts of ng mL⁻¹ to several µg mL⁻¹).

One important reason for the rather high LOD is that flames give rise to significant amounts of background radiation, which acts as a source of scattering for laser light. Many types of flames, supported on a variety of burners, have therefore been scrutinized for their applicability to LIF/LEAFS. Even if slot burners (which were specially designed for AAS by providing a long pathlength) were handy to use, they were found not to be suitable for the LIF/LEAFS technique. A variety of alternative burners have therefore been developed for the LIF/LEAFS technique – some with small holes or capillary tubes, and some surrounded by a sheet of inert
gas (most often N₂ or Ar) in order to reduce the effects of quenching that can result from the entraining of air and reduce the fluorescence yield.\(^{(150)}\)

Another way to improve the sensitivity and LOD of conventional flame LIF/LEAFS is to use a multipass configuration (using a flat mirror with a pierced hole in the perpendicular position together with a toroidal mirror).\(^{(149)}\) Using a flashlamp-pumped dye laser for excitation, Epstein et al. demonstrated that the LOD of Fe could be improved from 0.6 to 0.2 ng mL\(^{-1}\).

The field of flame LIF/LEAFS has been quite stagnant during latter years but an impressive exception is the multi-element analysis of river sediment for five elements using a modern tunable OPO system. Comparable or improved flame LEAFS detection limits over previous literature values were obtained for Co, Cu, Pb, Mn and Ti (2.0, 0.4, 0.2 and 0.9 ng mL\(^{-1}\), respectively).\(^{(154)}\)

### 4.4.4.2 Laser-induced Fluorescence/Laser-excited Atomic Fluorescence Spectrometry in Graphite Furnaces

If the actual detection limits turned out not to be as impressive as first anticipated when flames were used with the LIF/LEAFS technique, the results were soon found to be significantly more impressive when the ETA was used as atomizer. Detection limits well into the picogram per milliliter range and in the femtogram range were rapidly established. There are a number of developmental achievements related to furnaces, the optical system, detectors and detection strategies that have brought the LIF/LEAFS technique to a level where it stands today. Following the first LIF/LEAFS measurements in ETAs, which were made on graphite rods (see references 85, 157, 216, 218, 220–222), filaments\(^{(222)}\) and boats,\(^{(217, 219)}\) open cups rapidly became popular (see references 132, 160, 165–170, 178, 198, 203–208, 213–215, 221) owing to their better performance. For example, Goforth and Winefordner compared a graphite rod, a plain graphite cup and a slotted graphite cup for a number of elements and found that the rod worked well for volatile elements but gave insufficient atomization for less-volatile elements, and that the plain graphite cup gave the best overall results of these atomizers. They also compared the LOD for pyrolytic coating, a tantalum foil liner and a tantalum carbide coating of a graphite cuvette, and found the pyrolytic coating to give the best results.\(^{(221)}\)

It was meanwhile found by AAS, however, that open atomizers (e.g. rods, boats and cups) are impractical due to diffusion losses\(^{(249)}\) and vapor-phase interferences\(^{(250)}\) that occur in the cool zone above the atomizer. Similar effects were soon found for the LIF/LEAFS technique, for example by Bolshov et al.\(^{(203)}\) It was therefore concluded, first by Human et al.\(^{(157)}\) and Dittrich and Stärk,\(^{(218)}\) and later by others (e.g. Falk and Tilch\(^{(214)}\)), that graphite tubes provided the best atomization environment for analysis (see references 77, 79, 80, 121, 158–164, 171–177, 179–197, 199–202, 209–212, 214, 218, 220, 224–226). Dittrich and Stärk,\(^{(218)}\) and shortly after, Falk and Tilch,\(^{(214)}\) for example, demonstrated that the tube atomizer had an increased sensitivity over the rod atomizer. They attributed this to an increased residence time and a higher degree of atomization. Other advantages of the tube are a more homogeneous temperature distribution and a higher heating rate.\(^{(174, 218)}\)

The most important development of the optical system for LIF/LEAFS in an ETA is the front-surface detection (as was shown in Figure 7), which not only provides freedom from post-filter effects (see below) and the imaging of a larger interaction volume but it also has yet another distinct advantage over right-angle detection when it comes to ETAs – it can be applied directly to the atomizer without any modification of the furnace system. In addition, the use of reflective instead of refractive optics has also improved the performance of LIF/LEAFS in an ETA (because it provides chromatic-free light collection).

Regarding detectors, most LOD have been determined using PMTs. The ICCDs have not proven themselves to yield any better LOD than the PMTs under normal conditions. Their main advantage instead is that they can monitor the fluorescence background significantly more effectively than the PMTs and hence yield more reliable results when samples with complex matrices are detected.\(^{(189)}\) The ICCDs have also proven to be indispensable when efficient excitation–detection transitions are to be found in atoms with complicated atomic structure.\(^{(80, 187)}\)

The state-of-the-art performance of the LIF/LEAFS technique in an ETA is shown in Table 4, which displays the best LOD published so far for each element (see references 79, 158–160, 169, 170, 173, 174, 178, 179, 183, 187–190, 194–196, 199, 201, 203–206, 224, 225). Table 4 is based upon a compilation of around 200 LOD from the literature for the LIF/LEAFS technique in an ETA.

As can be seen from Table 4, quite a number of elements have LOD in the low femtogram range. For many elements, improvements of two to four orders of magnitude (with respect to the conventional AAS technique in an ETA) have been obtained. Elements that have poor LOD in the AAS technique because of furnace atomization problems (in general those that require high atomization temperatures, normally above 2500 °C) also have relatively poor LOD in the LIF/LEAFS technique. The LOD for these elements are limited either by memory effects in the graphite cuvette\(^{(80, 173, 178, 194)}\) or by blackbody radiation from the atomizer. Although the majority of the LOD have been measured using one-step excitation,
there are a few elements whose LOD have been obtained by using double-resonance fluorescence.

Molecular detection has found a certain (although limited) use for the assessments of some elements whose excitation wavelengths are difficult to access with laser light, e.g. halogens.\(^{121,177,192}\). In the case of fluorine, for example, a matrix of Mg was added to the sample (analyzed in a GF), leading to the formation of MgF, which could be detected by LEMOFS.\(^{177,192}\)

4.4.4.3 Laser-induced Fluorescence/Laser-excited Atomic Fluorescence Spectrometry in Other Atomizers

LIF/LEAFS has also been used in conjunction with other types of atomizers. Owing to the success of the ICP with conventional detection techniques, a number of investigations have been devoted to investigations of the use of this atomizer together with LIF/LEAFS.\(^{37,60,66,94,122,157,228-230}\) An early, mostly diagnostic, investigation of the use of the LIF/LEAFS technique with an ICP was performed by Omenetto et al.\(^{228}\) A more extensive demonstration of the analytical capability of the LIF/LEAFS technique applied to an ICP was made by Human et al. in 1984.\(^{157}\) The authors assessed LOD for a range of elements (Al, B, Ba, Ga, Mo, Pb, Si, Sn, Ti, Tl, V, Y, Zr and U). The LOD were found to be between 0.4 and 20 ng/mL. \(^{157}\) Atomic fluorescence from Ag, Au, Hf, Ir, Mo, Nb, Pd, Pt, Ru, Ta and Zr in an ICP was measured by Huang et al.\(^{229}\)

LOD found were in the 1.3–58 ng mL\(^{-1}\) range, with an LDR of over four orders of magnitude for most elements. Double-resonance ionic fluorescence has been used as an alternative to atomic fluorescence from Ca, Sr, Ba and Mg atoms in an ICP in order to improve on the sensitivity or to extend the number of accessible elements.\(^{94}\) The LOD for these four elements were 0.007, 1, 1, and 0.05 ng mL\(^{-1}\), respectively. Simeonsson et al.\(^{230}\) used both single- and double-resonance excitation for detection of atomic or ionic fluorescence from Ag(I), Au(I), Co(I), Cu(I), Ni(I), Pb(I), Pd(I), Pt(I) and Sc(II). The LOD for single excitations for these elements were found to be 0.8, 4.2, 15, 3, 5, 0.7, 3.9, 3.3 and 0.2 ng mL\(^{-1}\), respectively. The corresponding LOD for double excitation were 1.7, 6.0, 530, 5, 170, 8, 45, 29 and 13 ng mL\(^{-1}\), respectively. Their results show that double-resonance excitation in fact yields higher LOD than single-resonance excitation. The authors stressed, however, that the spectral selectivity for the double-resonance excitation technique should widely supersede that of the single-resonance excitation technique.

These studies show that the LOD for the LIF/LEAFS technique with an ICP are generally in the low nanogram per milliliter range, with a few exceptions such as ionic detection of Ca and Mg, which are well into the picogram per milliliter range.\(^{94}\)

Although the LIF/LEAFS technique is generally not very impressive for isotope detection, because most optical isotope shifts are smaller than the typical laser bandwidths or Doppler and collisional broadening mechanisms in most atomizers (with the exception for some actinides and lanthanides), it has been used for isotopic detection of uranium isotopes in complex matrices in an ICP.\(^{122}\)

LIF/LEAFS has also been applied to a hollow-cathode glow discharge, which served the purpose of being the atomizer (aqueous solutions were dried in graphite electrodes used as disposable hollow cathodes).\(^{231}\) LOD for Pb and Ir were 500 fg and 20 pg, respectively. A commercial hollow-cathode lamp (which has a very low background emission and excellent atomization characteristics) has also been investigated for its use for SAD (referring to the number of atoms in the interaction volume).\(^{232}\) An LOD for Pb of 1.8 fg (i.e. 0.0018 fg) in the laser beam was established. Work with a hot, hollow-cathode atomizer has also been performed.\(^{233}\) LOD for dried solutions of Co and Ni were 15 pg mL\(^{-1}\) and 5 ng mL\(^{-1}\), respectively. LIF/LEAFS measurements for trace detection in conducting solids (Fe in brass) have been performed by Travis et al.\(^{234}\) The LOD were below the microgram per gram level. LIF/LEAFS has also been applied to direct detection of U(VI) in solution, with a LOD of 40 pg mL\(^{-1}\).\(^{235}\)

### 4.4.5 Linear Dynamic Range

Although the LIF/LEAFS signal is linear with analyte concentration for small concentrations, pre-filter, self-absorption, and post-filter effects can degrade the linearity at higher concentrations.\(^{35,37,70,137,164,241}\) Pre-filter effects refer to the reduction in fluorescence signal that occurs because of absorption of laser light by analyte atoms on its way to (i.e. prior to) the interaction volume (the interaction volume is defined as the overlapping volumes of laser irradiation, atomic density and detection), whereas self-absorption refers to reabsorption of fluorescence light by analyte atoms within the laser-irradiated volume. Finally, post-filter effects refer to reabsorption of fluorescence light by atoms outside the irradiated volume (i.e. absorption of fluorescence by atoms within the detection volume but outside the illuminated volume). The risk for self-absorption and post-filter effects to occur is naturally higher for transitions that terminate in highly populated states (e.g. the ground state or in low-lying excited states) than for those transitions that terminate in short-lived excited states.\(^{38,164}\) Self-absorption can occur also for transitions terminating in relatively long-lived excited states mainly when continuous-wave excitation is used.

Because both pre-filter and self-absorption originate from absorption of light by atoms within the irradiated volume of atoms, these effects can be reduced by optically saturating the transition because optical saturation occurs when the rates of absorption and stimulated emission balance each other, a medium with optically saturated atoms is transparent at that particular wavelength.\(^{145}\) Post-filter effects, on the other hand, are not affected by the laser irradiation. Hence, they can cause significant reduction in the LDR even when the atomic transition is saturated. On the other hand, post-filter effects can be eliminated by using front-surface detection (because all atoms viewed by the detector are illuminated by laser light).\(^{35,37,38,156,164,174,176,195,221,224,248}\) This implies that the front-surface mode of detection yields smaller post-filter effects and hence a larger LDR than do systems with right-angle detection.\(^{156,164,174,176,195,221,224,248}\)

Dynamic ranges of five to seven orders of magnitude have been demonstrated for several elements using front-surface detection.\(^{164,175,212,221}\)

### 4.4.6 Selectivity

The selectivity of the LIF technique is excellent due to a double selectivity for the conventional single-resonance fluorescence spectrometry technique and a triple selectivity for the double-resonance technique. As was discussed in connection with concomitant scatter and nonanalyte atomic fluorescence above, a concomitant species needs to have a spectral overlap both in the excitation as well as in the de-excitation processes in order
to yield a background signal. There are very few such examples documented in the literature. One exception was the study of Sb in estuarine water, as shown above in Figure 10.

4.4.7 Applications
Although the limited space in this theory and instrumentation review precludes any detailed analysis of the applicability of LIF/LEAFS, a few examples can be given.

4.4.7.1 Laser-induced Fluorescence/Laser-excited Atomic Fluorescence Spectrometry in Flames
The flame LIF/LEAFS technique has been used for a limited number of applications. Compilations can be found in the literature.\(^\text{(36,68)}\) One example is Fe detected in simulated fresh water, unalloyed copper and fly ash. Other examples are the detection of Pb in blood\(^\text{(155)}\) and the determination of Ni and Sn in various reference materials (riverine water, unalloyed copper and fly ash).\(^\text{(156)}\) A multi-element LIF/LEAFS analysis of river sediment in flames for Co, Cu, Pb, Mn and Ti using a modern tunable OPO system, encompassing 640 measurements in 6 h with triplicate measurements of all solutions and aqueous calibration curves, with a relative standard deviation (RSD) precision better than 5%, was done by Zhou et al.\(^\text{(154)}\) Flame LIF/LEAFS has also been coupled to high-performance liquid chromatography (HPLC) for speciation. Walton et al., for example, detected various organomanganese and organotin species by HPLC and flame LIF/LEAFS. The detection limits for organomanganese species ranged from 8 to 22 pg of Mn.\(^\text{(156)}\)

4.4.7.2 Laser-induced Fluorescence/Laser-excited Atomic Fluorescence Spectrometry in Eletrothermal Atomizers
There are a large number of applications of the LIF/LEAFS technique in ETAs. A recent compilation is given in the review by Hou et al.\(^\text{(38)}\) An early example is the detection of Cd and Pb in Antarctic and Greenland snow and ice by Bolshov et al.\(^\text{(169)}\) (with an LOD of 0.5 fg). Thallium, manganese and lead were detected by slurry sampling in food and agriculture standard reference materials by Butcher et al.\(^\text{(175)}\) The technique has also been used for the assessment of trace levels of gold in size-segregated, atmospheric particulate samples.\(^\text{(158)}\) The simultaneous monitoring of entire fluorescence spectra by the use of an ICCD made possible the detection of Ni in various aqueous standard reference samples with sodium concentrations ranging from micrograms to tens of milligrams per milliliter (riverine water and estuarine water) with good accuracy and precision.\(^\text{(187)}\) The Zeman correction technique has been used for assessment of Mn in a zinc chloride matrix and brain tissue using resonance fluorescence.\(^\text{(171)}\)

4.5 Diagnostic Capabilities
The LIF/LEAFS technique has been used by numerous authors for a variety of diagnostic studies.\(^\text{(60,252)}\) Example of entities that have been studied are temperatures,\(^\text{(60,253–256)}\) number densities,\(^\text{(35,87,257–259)}\) quantum efficiencies,\(^\text{(260)}\) lifetimes of atomic states in flames,\(^\text{(69,261)}\) spatially resolved atomic distributions in flames,\(^\text{(67)}\) laser-induced flame chemistry processes,\(^\text{(262,263)}\) collisional effects in flames,\(^\text{(264)}\) collisional mixing rates of excited atomic states in flames,\(^\text{(78,86)}\) the role of chemical reactions on saturation curves,\(^\text{(265)}\) excitation–detection wavelength combinations of atoms with complex atomic structure by the use of an ICCD,\(^\text{(80)}\) memory effects in GFs,\(^\text{(188)}\) and the Zeeman effect.\(^\text{(163,193)}\) Of special importance is the fluorescence dip,\(^\text{(97–99,266)}\) which has been used for studies of quantum efficiencies,\(^\text{(267)}\) radiative transfer,\(^\text{(268)}\) ionization depletion\(^\text{(99)}\) and autoionizing cross-sections.\(^\text{(269)}\) A thorough study of the capabilities of performing time-resolved investigations for diagnostic purposes was made by Omenetto and Matveev.\(^\text{(270)}\) Further discussions about the diagnostic capability of the LIF/LEAFS technique are given by Omenetto.\(^\text{(127,266)}\)

4.6 Conclusions and Outlook
LIF/LEAFS is a technique that has clearly demonstrated its usefulness for analytical applications. The most impressive performance has been achieved with the GF as an atomizer. The most versatile detection systems for LIF/LEAFS today are based upon a combination of front-surface detection and chromatic-free reflective optics (either by a pierced curved mirror or a pierced flat mirror followed by a curved mirror). Double-resonance fluorescence can bring high detection powers to some elements. The use of an ICCD when samples with complex matrices are analyzed is advantageous. LOD in the low femtogram range have been obtained for a number of elements. Owing to its double (or triple) selectivity, the LIF/LEAFS technique shows an extraordinary selectivity. Moreover, the LDR has been found to be large (five to seven orders of magnitude has been demonstrated). This implies that the LIF/LEAFS technique in an ETA can rival most other analytical techniques for trace element analysis.

Work has also been done with regard to the SAD capability of the LIF/LEAFS technique. It is clear that the LIF/LEAFS technique is capable of detecting the presence of one single atom in quiet surroundings (e.g. in a vacuum). However, the SAD capability of the technique seems more difficult to address when the technique is coupled to practically useful atomizers. It is clear that the graphite tube (and in particular the transversely heated tube) so far provides the best (although not the ideal) atomizer for practical analytical work. Work with other,
quieter atomizers, e.g. a hollow-cathode lamp, might bring down the LOD of the technique, although at the price of less versatile and less user-friendly instrumentation.

Looking back at the development of the LIF/LEAFS technique in an ETA – with the improved knowledge about the underlying principles for the technique that has been gained throughout the years, which in turn has resulted in more efficient experimental set-ups and detection methodologies – and speculating into the future, one can conclude that it would be surprising if the technique were not to be quoted with even better LOD, selectivity and LDR values a few years from now.

5 LASER IONIZATION SPECTROMETRY

5.1 Laser-enhanced Ionization versus Resonance Ionization Spectrometry

As was alluded to in the Introduction (section 1.4.2), there are basically two different laser-based spectroscopic ionization techniques with good potential for analytical applications: LEI and RIS. The main difference between the two is that LEI is performed in conventional atmospheric pressure atomizers (flames, furnaces, etc.) and RIS is performed under vacuum conditions.

Because atoms in atmospheric pressure atomizers are exposed to a high collision rate, they also experience a certain thermal ionization. As was discussed earlier, this thermal ionization ionizes excited atoms at a rate faster than ground-state atoms. Hence, this thermal ionization can be increased significantly by exciting atoms in high-collision media by laser light. By applying an electrical field across the interaction volume, the increased ionization rate is then detected as an increase in the current through the atomizer, which constitutes the signal in LEI spectrometry. In the environment to which RIS is applied, there is no such thermal ionization. This implies that although the laser light has only to excite selectively the analytes in the LEI techniques (the ionization is provided by the existing thermal ionization process in the atomic reservoir), the laser light has to be used for both selective excitation and ionization of the analytes in RIS. Although the RIS technique has shown some extraordinary properties (i.e. SAD and extremely high elemental selectivity, especially when coupled to a mass spectrometer for detection of the ions produced), the fact that atomization of the sample in general is performed under vacuum conditions puts some restrictions on the practical applicability of the technique. It will therefore be covered in less detail in section 5.8. The reader is referred to the literature for a detailed description of the technique.

5.2 Laser-enhanced Ionization Spectrometry – An Introduction

LEI is a technique that originates from a finding by a group of scientists at the National Institute of Standards and Technology (NIST, formerly National Bureau of Standards NBS), Gaithersburg, Maryland, USA, in 1976. Green et al. found that atoms in a flame irradiated with laser light experience an increased ionization rate if the laser light is resonant with a transition in the atoms. This increased ionization could be detected most easily by applying an electrical field across the flame and measuring the corresponding increase in current. This effect was originally termed “optogalvanic detection” for a few years by the American community, a name that rapidly became used exclusively for the phenomenon in discharges. The name LEI was used for the “optogalvanic” phenomenon in flames for the first time in 1979. The technique has also appeared under a variety of other names throughout the years, e.g. (stepwise) photoionization in flames (primarily by the Russian community), dual laser ionization, laser-assisted ionization, laser-induced ionization, laser step-photoionization, or just stepwise photoionization.

As was alluded to previously, it was found early on that laser light in fact does not need to ionize the atoms under study in LEI spectrometry; it is sufficient to excite them (e.g. promote ground-state atoms to an excited state) in order to create an increased rate of ionization. This led to the conclusion that the laser light enhances an already existing thermal ionization process, sustained by the heat of the flame, which ionizes excited atoms at a higher rate than it does for unexcited (ground-state) atoms. A more concise terminology of the technique would therefore have been laser-enhanced collisional ionization, an expression that never came into use.

The common denominator for all atomic reservoirs (atomizers) to which LEI can be applied is, therefore, that they must possess a certain omnipresent thermal ionization that converts photons absorbed by the atoms under study into freely movable charges (electrons and ions). This implies, in turn, that the atomizer performs two functions simultaneously in LEI spectrometry. It renders an atomization of the sample and provides a collisional excitation of the laser-excited atoms.

The LEI technique has most often been used with flames as atomic reservoirs, although GFs, plasmas, discharges, cells and thermionic diodes also have been used but to a significantly lesser extent than flames. We will therefore direct most of this presentation of LEI to its use in flames and only briefly mention its use together with other atomizers (e.g. GFs and plasmas). Moreover,
in a perspective of analytical chemistry, LEI spectrometry with optogalvanic detection in discharges or thermionic diodes is of less interest because these types of atomizers do not provide for any simple means of introducing and atomizing an unknown sample into the atomic reservoir. Optogalvanic detection in discharges has become of more interest for spectroscopic investigations and as a technique for wavelength calibration, and therefore will not be discussed further here. The only exception is the development by Petrucci and Winefordner of a sensitive photon detector based upon the optogalvanic effect. The reader is therefore directed to the literature for more information about optogalvanic spectrometry.

5.3 Previous Reviews

The field of LEI spectrometry has been reviewed previously by a number of authors. An early but very illustrative review is that by Travis et al. The work by Green and Seltzer is a thorough and easy-reading review of the status of the field up to 1989. A contemporary review, although somewhat more focused upon the principles of the technique, is that of Axner and Rubinsztein. Butcher has recently provided an updated complement to the review of Green and Seltzer. The most comprehensive review, however, is given by a recent book dedicated to the field. This book covers the fundamental mechanisms of LEI in terms of the production of ions and the signal detection, the analytical performance of LEI in flames, applications of LEI and nonflame reservoirs for LEI spectrometry, and the interplay of LIF and LEI in different atomic reservoirs. Although mostly used for the detection of atoms, the LEI technique has also been used for the detection of molecules, which has been reviewed specifically by Webster and Rettner.

5.4 Instrumentation

5.4.1 Typical Set-up

Because LEI mostly has been used with flames as atomizers, the flame LEI set-up shown in Figure 11 will serve the purpose of illustrating a “typical” LEI instrumentation. In short, light from a laser system, most often a pulsed dye laser system, is directed into a flame at a height where there is a sufficient atomic population of the analyte species to be detected. An electrical field is established in the interaction volume by applying a potential (most often ranging from −1 to −2 kV) between...
an electrode immersed in the flame (or alternatively between two external electrodes placed on each side of the flame) and the burner head (which is the head at ground potential). In order to be able to detect the charges created, the burner head has to be isolated electrically with respect to ground, with only a controlled electric path (accomplished by a resistor) to ground potential. When pulsed excitation sources are used, as is most often the case, a pulsed LEI current will result in this path. This current pulse is extracted from the direct current (DC) (originating from the thermal ionization) by a capacitor before it is converted to a voltage pulse by a current-to-voltage amplifier of suitable trans-impedance gain. The output signal is most often monitored by using a boxcar integrator whose detection window is set equal to or slightly longer than the resulting voltage pulse (often around 1 µs). The output from the boxcar is most conveniently fed into a laboratory computer.

5.4.2 Atomizers

5.4.2.1 Flames Most flames used for LEI have been supported on commercially available slot-burner units (including nebulizer units) developed for the AAS technique. The elongated form of the slot-burner-supported flame (normally 5 or 10 cm) is suitable for LEI because it gives a long interaction region (which in turn makes interaction with a large number of analytical species per laser pulse possible). In addition, the use of commercially available slot-burner units has also meant that the LEI technique has been able to benefit from the development of burner and nebulizer units. A typical pneumatic nebulizer, which converts the sample solution into a liquid aerosol, has a liquid sample uptake rate of around 5 mL min⁻¹ and an efficiency of about 10% (the rest being drained to waste).

All standard types of flame used for AAS have been used for LEI (e.g. air–acetylene, nitrous oxide–acetylene, air–hydrogen), with the air–acetylene flame being the most popular. The reason for this is that this flame constitutes a good compromise between a high degree of atomization, relatively low occurrence of chemical interferences and a high degree of thermal ionization. The higher-temperature flames (e.g. the nitrous oxide–acetylene flame) have a better degree of atomization of refractory elements and a higher degree of thermal ionization (and thereby collisional ionization), which would justify their use in LEI spectrometry. A disadvantage is that the higher degree of thermal ionization also produces a larger background signal (from which the LEI signal has to be extracted). This implies that the detection power of atoms that atomize readily in air–acetylene or air–hydrogen flames decreases when being detected in a nitrous oxide–acetylene flame. For nonvolatile elements, however, the hotter nitrous oxide–acetylene flame offers an advantage.

The cooler flames (e.g. hydrogen flames), on the other hand, benefit from a lower background ionization, which in principle should give opportunities to lower detection limits for those elements that atomize readily in such flames. The lower background ionization rate of the hydrogen flames, however, is not such an advantage in reality as might be expected. The reason is that when samples containing “normal” concentrations of EIEs are detected, the background ionization rate is dominated by thermal ionization from the EIEs rather than the flame background ionization. The cooler flames are instead limited by a lower degree of atomization and a lower collisional ionization rate, resulting in a poorer LEI detection power for most elements. In addition, the cooler hydrogen flames are more susceptible to chemical interferences, which limits their use for practical purposes. The cooler flames, however, are useful for LEI detection of alkali metals, because these ionize readily also in the cooler flames (and in fact exist with a larger fraction of neutral atoms).

5.4.2.2 Plasmas Only a limited number of studies concerned with the use of plasmas as atomizers for LEI have been carried out. The reason is that the plasma does not offer the same suitable environment for the LEI technique as does the flame. The main reasons for this are the following: firstly, the ion fractions in ICPs are much larger than in flames, which implies that the neutral atom population (i.e. those that are available for excitation) is smaller than in a flame for the atoms that already atomize readily in a flame; secondly, the electrical environment around a plasma is harsher than around a flame, implying that the radiofrequency pick-ups become more severe; thirdly, the electron density in a plasma is several orders of magnitude larger than in the flame, which makes it more difficult to detect the laser-induced creation of charges. LEI detection in an ICP has therefore been performed either in the tail end of the plasma or in a power-modulated plasma. Attempts have also been pursued to detect the laser-produced ions with a mass spectrometer rather than electrically.

5.4.2.3 Electrothermal Atomizers The increased LOD that followed when the flame was substituted with the GF for the AAS and the LIF/LEAFS techniques also encouraged the field of LEI spectroscopists to move to the GF. Early attempts using the GF as an atomizer for LEI were therefore made by Gonchakov et al., Bykov et al., Magnusson et al. and Sjöström.

One drawback with LEI in a GF is that the GF does not allow for any apparently efficient geometry for the
charge collection as does the flame in flame LEI (see section 5.4.4.2). Therefore, although the discussion about electrode design for flame LEI has been conveniently placed in section 5.4.4.3, together with a discussion about the principles for the charge collection process, this is not possible in the case of LEI in a GF because the performance of this technique is strongly dependent on the interplay between the GF and the charge-collection electrode(s).

Gonchakov et al., who used a graphite cup as an atomizer,\(^\text{301}\) used a circular wire probe placed above the cup. Magnusson et al., on the other hand, who used a large graphite tube (HGA-72), placed the charge-collecting probe inside the tube parallel with the laser light.\(^{329,330}\)

Both Magnusson et al.\(^{329,330}\) and Gonchakov et al.\(^\text{301}\) investigated the influence of various voltages and potentials applied to the probe. Although the first work by Magnusson et al. concluded that the best reproducibilities and S/N ratios were obtained with a negative potential applied to the electrode,\(^{329}\) they found contrary results in their second study.\(^{330}\) With a negative voltage, the signal duration was determined by the time constant of the resistance–capacitance (RC) high-frequency cut-off filter (1µs or 100 ns, depending on the resistor value). The total signal (integrated over time), however, was found to be independent of the RC cut-off frequency. With a positive voltage, the signal lasted around 20 µs, and was found to be significantly larger than that obtained with a negative probe potential. It is as yet unclear as to whether this can be explained by the conventional model for charge collection and signal apportionment (based upon the difference in mobility between electrons and ions) developed by Travis and Turk (section 5.4.4.2).\(^{40}\) Magnusson et al. suggested that signal-enhancing space–charge effects, similar to what exists in thermionic diodes, might play a role. Also Gonchakov et al. found a signal-enhancing effect. They state that: “The signal amplification coefficient arising from the avalanche ionization of the probe was about 100. This was verified by replacing the tungsten probe with a stainless steel probe, for which the signal proved to be 100 times smaller. A polarity change at the probe reduced the signal by four to five orders.”\(^\text{301}\)

In addition, it was concluded early on that the long-term reproducibility was not satisfactory for LEI in a GF. Magnusson concluded, for example, that the reproducibility could be improved by replacing the wire electrode with one of a solid graphite rod.\(^{331}\) In this work, the laser beam was enlarged so that it filled the entire tube, and the electrode was placed in the center and held at zero potential. They reported on a large variation in the duration of the signal pulses when a positive potential was applied. These and similar results indicate that the signal collection process is not yet fully understood in LEI spectrometry in a GF.

It was found early on that the large currents from the heating system induced currents to the probe. In order to minimize these effects, Magnusson et al. synchronized the triggering of the laser with the 50-Hz power line. In this way, the fluctuations of the induced disturbances on the signal could be virtually eliminated.\(^\text{329}\)

Both thermionic and photoelectric emission of electrons from surfaces (e.g. the electrode) had been noticed previously from flame LEI measurements when an uncooled metal surface was inserted into the flame or when intense UV light struck a surface, respectively. The same effects were found also for the LEI technique in a GF. Because a large electronic emission rate can lead to suppression of the analytical signal or electrical breakdown, it is not impossible that this might be one reason for the poor reproducibility of the LEI in a GF. Irrespective of whether this is the case, it will limit the applicability of the technique considerably.

Magnusson et al. showed that the effects of photoelectric emission could be reduced by carefully aligning the laser beam sufficiently far from the electrode.\(^\text{330}\) It was noticed, however, that the heating of the furnace made the atmosphere act as a thermal lens, thus focusing the light during heating and defocusing it during cool-off, which can be a source of signal fluctuation.\(^\text{330}\) Further investigations reported on the existence of dual peaks for LEI in a GF.\(^\text{330}\) The same work also investigated, among other things, the influence of different protective gases on the thermionic emission of electrons and found significantly lower thermionic emission in N\(_2\) than in Ar.\(^\text{330}\)

An alternative approach to the careful aligning of the laser beam away from the electrode, first suggested by Magnusson\(^\text{331}\) and then investigated practically by Sjöström,\(^\text{332}\) was to separate spatially the atomization volume from the charge detection volume so as to overcome some of the problems occurring in the previous construction. A T-shaped furnace was constructed in which the atomization took place in the “base” of the T while the detection was carried out in the “bar” part of the furnace. This measurement section consisted of two stainless-steel plates, separated by Teflon insulation, with the outer plate held at −500 V. By separating the atomization and detection regions, less thermionic emission of electrons resulted.

Chekalin and Vlasov achieved a separation of the atomization and detection regions by placing the charge-collecting electrode above the dosing hole of a graphite tube while the laser beams were directed outside the tube (between the electrode and tube).\(^\text{333}\)

The common denominator of all these LEI measurements in a GF is that none of them made use of the most modern and up-to-date furnace technology. Butcher et al. used a modern HGA-500 (Perkin-Elmer) furnace...
and constructed a system with a moveable probe that was introduced automatically into the furnace shortly after the onset of the atomization so as to minimize the amount of thermionic emission.\(^{[334]}\) They investigated the LEI and GF instrumentation with respect to a number of parameters in order to find the optimum conditions. Optimization of the atomization temperature for iron showed that no signal was obtained at temperatures exceeding 2000 °C. The loss of signal was attributed to the presence of a large thermionic emission of electrons. As a consequence, only temperatures up to 1900 °C were separated from each other. This reduces, among other reasons, atomization and excitation–ionization–detection in the laser beams. By this procedure, the regions of evaporation are delayed until the sample is well into the flame. Excitation and ionization then take place at a lower temperature than atomization, because evaporation normally takes place at a lower temperature than atomization, atomization is delayed until the sample is well into the flame. Excitation and ionization then take place at a suitable height above the rod (determined by the height of the laser beams). By this procedure, the regions of evaporation, atomization and excitation–ionization–detection are separated from each other. This reduces, among other things, problems associated with thermionic emission from the graphite rod that otherwise limit the detection power and matrix effects.

Smith et al. pursued an alternative route in order to separate the vaporization from the ionization detection.\(^{[339]}\) The output of a GF was coupled into the argon flow of a miniature flame system.

5.4.2.5 Cells Detection of mercury differs from most other elements in that it already has a high vapor pressure at room temperature. No heated atomizer is therefore needed for mercury – a room-temperature atomic reservoir suffices. Mercury can therefore be measured directly in a cell. The groups of Winefordner and Omenetto have made extensive studies of the applicability of detection of mercury by the LEI technique (section 5.5.3.6).\(^{[178, 270, 341–346]}\)

5.4.2.6 Thermionic Diodes Yet another alternative to the detection of laser-excited atoms by electrical means is the thermionic diode. Thermionic diodes are known to be extremely sensitive detectors for ions,\(^{[347]}\) having a large dynamic range (over four orders of magnitude) and a very high gain (10⁶ or larger).\(^{[318]}\) The thermionic diode consists basically of a cylindrical anode in which an axially mounted cathode filament, heated by a DC, is mounted. No bias is needed to run the thermionic diode in a space-charge-limited mode. The ions produced by laser irradiation will be trapped within the negative space-charge cloud. Their presence reduces the space charge, which can be detected as a change in the diode current.\(^{[348–352]}\)

Owing to its construction, the thermionic diode is most suitable for continuous-wave laser excitations. Although the first experiments were made with continuous-wave dye lasers, diode lasers have been used more frequently lately.\(^{[353–359]}\) An improved type of thermionic diode that is suitable for analytical trace element analysis in samples with low vapor pressure has been constructed by Franzke et al.\(^{[354]}\) By inserting a grid between the atomizer and the thermionic diode detector, and with appropriate biasing of grid and atomizer, the perturbation of the space charge due to the emission of thermal ions and electrons from the surface of the atomizer could be eliminated. The thermionic diode is also suitable for Doppler-free spectroscopy, which allows for precise isotope determinations.\(^{[355–357]}\) It has also been found suitable for diagnostic purposes, i.e. the determination of collisional cross-sections and energy transfer rates.\(^{[353–363]}\)

5.4.3 Laser Sources As the selectivity of the LEI technique lies solely in the excitation step(s), narrow-band tunable laser systems must be used. Although the first demonstration of the LEI technique utilized a continuous-wave dye...
laser system (based upon an argon ion laser,\cite{277}) most subsequent work has been done using pulsed dye laser systems pumped by excimer lasers (see references 72, 74, 82–84, 89, 90, 95, 99, 109, 173, 181, 327, 329, 336, 364–381), Nd:YAG lasers (see references 294, 322, 328, 365, 382–386), nitrogen lasers (see references 91, 322, 328, 389, 387, 388), flashlamps (see references 74, 293, 306, 389, 390) or copper vapor lasers\cite{238} (with the two first types being by far the most used). A smaller number of investigations have used continuous-wave lasers (tunable diode lasers,\cite{391} argon- or krypton-ion-laser-pumped dye lasers,\cite{392} or atomic line lasers\cite{360}). As was alluded to earlier, the main reasons for the popularity of pulsed lasers is that they produce UV light (most atoms require UV light for efficient excitation) and saturate the transitions more easily than do continuous-wave systems, and they can produce a large signal over a short period of time (thereby maximizing the S/N ratio). A disadvantage with pulsed laser systems is the poor duty cycle.

5.4.4 Detection Equipment

5.4.4.1 Principles The most distinctive aspect of LEI is the charge-collection process. In LEI, the charge created as a consequence of laser illumination (i.e. the enhanced ionization rate) is detected electrically by applying an electrical potential across the volume of interaction. Hence, the atomic reservoir (e.g. the flame) is part of an electrical circuit. The applied potential gives rise to an electrical field that separates the charges created. The movement of the charges in the electrical field, in turn, gives rise to an induced current in the rest of the electrical circuit. This current is converted to a voltage by a current-to-voltage transducer (often termed amplifier), which thus constitutes the output signal of the LEI instrumentation. This implies that LEI differs from most other laser-based spectrometric techniques (e.g. LIF/LEAFS) because it does not require any light-detecting equipment.

5.4.4.2 Charge-collecting Electrical Field Although the electrical field strength between a cathode and an anode is constant under vacuum conditions, the thermal production of charges in a flame will give rise to a nonuniform electrical field strength. The cathode will attract the thermally created positively charged ions and the anode will attract the electrons. However, because the mobility of the electrons is about two to three orders of magnitude larger than that of the ions, they will be extracted more rapidly from the flame than the ions, leaving a certain density of positively charged ions behind (distributed with their highest density close to the cathode, decreasing in the direction of the anode). Hence, the flame will exhibit a certain positive charge. The presence of a net charge will give rise to a gradient in the electrical field. Because the highest density of ions is found close to the cathode, the largest field gradients will also be found there. This implies that the electrical field strength will decrease monotonically in a direction towards the anode. Depending on the potential applied, the distance between the burner head and the immersed cathode, and the amount of thermally produced charges, there will either be a finite but monotonically decreasing electrical field strength in all positions between the cathode and the burner head, or an electrical field strength that will be reduced to zero at a position before the anode. In the latter case, which can occur when there is a high thermal production of charges in the flame, the flame can be considered to be composed of two distinct regions: a positive ion space-charge region, often referred to as the cathode sheath or simply the sheath, which extends from the cathode to some intermediate position in the flame at which the electrical field strength becomes zero; and a part extending from the anode (the burner head) to the position in the flame in which there is no electrical field (hence constituting an unperturbed region in the flame).

In order to be able to detect the increased ionization rate, the charges have to be created in a region where there is an electrical field that can separate the charges. This implies that only charges created in the sheath will contribute to the detectable signal.\cite{536}

In addition, and as discussed in the literature in more detail, the LEI signal consists of two parts: one related to the movement of the electrons and one to that of the ions.\cite{307,536} Because the mobility of the electrons is two or three orders of magnitude larger that of the ions, the electronic signal will last only a fraction of the ionic signal. Moreover, because the area of the signal versus time curve represents the relative potential passed by each type of particle, they are of roughly equal size, implying that the electronic signal is not only shorter but also about two or three orders of magnitude higher than the ionic signal. Detection of only the electronic part of the LEI signal (whose duration is about 1 μs) has been shown to yield better S/N than detection of the entire signal (with a microseconds duration) owing to the significantly smaller amount of noise detected with the smaller gate.

5.4.4.3 Electrode Design A variety of electrode designs for flame LEI have been used and evaluated throughout the years. The first set-ups used electrodes (plates or rods) placed in close proximity to, but outside, the flame. The electrodes had either different polarity (giving rise to a mainly horizontally directed electrical field across the flame) or the same polarity (acting as a common cathode with respect to the burner head so as to produce mainly a vertically directed electrical field in the flame). It was soon found, however, that the best
practical performance (for best immunity to interferences from so-called EIEs; see section 5.5.4.1 for details) could be obtained using a cathode immersed in the flame and directing the laser beam close to the electrode. It has been demonstrated repeatedly that the immersed cathode clearly outperforms the external cathodes as soon as samples with any substantial amounts of EIEs are analyzed.  

5.5 Analytical Performance

5.5.1 Sensitivity

5.5.1.1 Optimum Laser-enhanced Ionization Transitions

A great deal of work in the field of LEI has been performed with the aim of finding the best/most suitable excitation wavelengths for various elements. It is obvious that whenever there are a number of transitions that all can be optically saturated by the laser light, the highest sensitivity will be obtained for the one that excites the atoms to the highest possible energy level (i.e. as close as possible to the ionization limit). However, because the transition probability (and hence the laser-induced excitation rate) rapidly decreases as a function of principal quantum number of the upper state, transitions to high-lying states will in general not be saturated by light from normal pulsed dye laser systems (which is illustrated in Figure 13). The question of which transition is the most sensitive in a given element then arises.

A systematic study of this concept was made by Axner. Based upon a simple model (assuming that the transition probability from the ground state to excited states decreases with the principal quantum number cubed, as it does for transitions to Rydberg states, assuming no optical saturation, and a particularly simple form of the ionization efficiency, namely a pure Boltzmann factor), he predicted that the transitions to states positioned approximately 1.7$kT$ below the ionization limit should show the highest LEI sensitivity for one-step excitations. In an acetylene–air flame with a temperature of 2500 K, this corresponds roughly to 3000 cm$^{-1}$, which for the case of Na and Li (the pilot elements in many investigations) corresponds to the 7p and 6p states, respectively. Measured LEI sensitivities confirm these simple estimates fairly well. The highest LEI sensitivity (for unsaturated transitions) for Na has been found for the 3s–6p transition (i.e. to a state approximately 4150 cm$^{-1}$ below the ionization limit), whereas the 2s–5p and 2s–6p transitions for Li have been shown to have approximately the same sensitivity. The small discrepancy between prediction and findings was explained by the use of an oversimplified expression for the effective ionization rate for excited atoms. The same work also predicted the most sensitive unsaturated one-step transitions for a number of other elements (K, Rb, Cs, Mg, Ca, Sr, Ba, Al, Ga, In, and Tl) using real transition probabilities rather than asymptotically extrapolated values. Because many elements have approximately the same level structure among the excited states, one can conclude that the most sensitive one-step transitions for LEI (for unsaturated transitions) are those that excite the atoms to states approximately $2–3kT$ below the ionization limit.

5.5.1.2 Ionization Yield

The ionization yield, defined as the fraction of illuminated atoms that are ionized as a consequence of laser irradiation, $Y_{\text{ion}}$, is a convenient quantitative measure of the sensitivity of the LEI excitation–ionization process. It has been found that the ionization yield can approach unity for pulsed as well as continuous-wave excitations for elements with low ionization potential. For example, Smith et al. determined the ionization yield of Li atoms excited to the 2p and 4d states by pulsed lasers in an acetylene–air flame. The authors concluded that approximately 60% of all the atoms were ionized following a stepwise excitation to the 4d state. Axner et al. measured ionization yields of up to 80% for Na atoms excited to the 7d state in a two-step process (3s–3p–7d) using a pulsed excimer laser system. Unity (or close to unity) ionization depletion from states further away from the ionization limit (the 3p state in Na in this particular case) has been demonstrated using continuous-wave excitation by Schenck et al. The increased illumination time for continuous-wave excitations compensates for the lower ionization rate of the 3p state.

5.5.1.3 Two-step versus One-step Laser-enhanced Ionization

As was alluded to earlier, a one-step excitation
is not sufficient to obtain a high ionization yield for elements with higher ionization potential. An alternative then is to excite the atoms under study in a two-step excitation process, as was discussed in section 3.4. The two-step versus one-step signal enhancement in LEI, defined as \( S_{12}/S_1 \), where \( S_{12} \) and \( S_1 \) are the two-step and one-step LEI signals, respectively, has been found to range from unity (i.e., no enhancement) to a few thousand, depending on element, choice of transitions, irradiances, etc. The use of two-step LEI will thus not only provide a larger sensitivity to the elements with a moderate or a high ionization limit but will also improve on the selectivity because it enhances the signal from the analyte significantly more than that of the background (see section 5.5.5.2).

### 5.5.1.4 Ionization Efficiency

Axner and Berglind determined a closely related entity, referred to as the ionization efficiency (defined as the probability that an excited atom will ionize before returning to the ground state), for excited \( np \) states in Na and Li. They found that the ionization efficiencies for these elements were considerably higher than those given by a simple Boltzmann factor (close to unity for states within 1 \( kT \) from the ionization limit and around 50% for states 2.5 \( kT \) below the ionization limit), thus supporting the discussion above (section 3) about an effective ionization rate that is larger than a single state-specific ionization rate.

### 5.5.1.5 Overall Efficiency

There have been several attempts to model the overall efficiency of LEI based upon the basic assumptions given above. The total number of charges created (per laser pulse), for example, can, in general, be written as a product of the density of analyte species, the interaction volume, and the ionization yield. It has been found, however, that such descriptions do not always agree with the experimental findings with expected accuracy. Although the dependence of most parameters (e.g., laser pulse energy and analyte concentration) is well understood, not all dependencies have yet found a satisfactory explanation. The area dependence is such an unexplained feature. In fact, the discrepancy between predicted and experimental behavior has been so extensive that not one single work has yet been able to address successfully this seemingly simple matter for the LEI technique.

It is rather straightforward to argue that there should be an optimum laser beam area for a given laser pulse energy. As long as the transition is saturated, and the cross-section of the laser beam is smaller than the distribution of the analyte atoms in the part of the atomizer in which there is a sufficient charge collection efficiency, the total number of charges created can be increased by enlarging the laser beam area. As the beam area becomes larger, the degree of optical saturation will decrease, eventually implying that the linear excitation regime will be reached. In this case, any further defocusing will no longer increase the number of charges created (for a one-step LEI case) because the increasing number of atoms illuminated will be balanced by a decreasing fraction of atoms excited in the interaction volume. Eventually, when the beam area becomes larger than the distribution of the analyte atoms in the atomizer (or the part of the atomizer in which there is a sufficient electrical field for collection of the charges created), the total number of charged created or detected should decrease. However, this behavior has never been verified experimentally.

#### 5.5.1.6 Influence of ‘Scattered Laser Light’

A possible explanation as to why this discrepancy exists was given by the findings of Sjöström and Axner when they found that the signal strength of the LEI technique could be influenced significantly by what they referred to as ‘scattered laser light’.

Figure 14 shows the results from an experiment on Sr atoms in an acetylene–air flame. A laser with a small beam diameter (in this case 2 mm) was scanned across the \( 5s^2 \, ^1S_0 – 5s \, 5p \, ^1P_1 \) transition around 460.733 nm for four different laser pulse energies in Figure 14(a). A distinct peak from Sr atoms is clearly visible in all the four scans. Worth noticing is that even though the irradiance of the light was increased by a factor of 45 from 12 to 550 kW cm\(^{-2}\), the peak signal only increased by a factor of 2. This behavior is normally interpreted as a manifestation of optical saturation. However, a simple modeling of the behavior of a two-level system shows a clear discrepancy with respect to the experimental findings. The reason is that an optically saturated system shows saturation broadening when the laser wavelength is being scanned over the transition. Saturation broadening originates from the fact that a laser beam that strongly saturates the transition on resonance also saturates the transition when being slightly detuned. This implies that the profile broadens. The result of a modeling of a two-level system (with some photoionization) that replicates the peak values of the experimental curves in Figure 14(a) are shown in Figure 14(b). It can be seen clearly that there is a significant discrepancy between prediction and experimental findings when it comes to the width of the curves.

In order to understand this discrepancy, additional experiments were made. Figure 14(c) shows the results from a corresponding set of experiments for a larger beam area. In this case, the beam area was enlarged 16 times (the beam diameter was expanded from 2 to 8 mm), as was the beam pulse energy (so as to preserve the irradiance of the light and degree of optical saturation). It was then found unexpectedly that the signals were only marginally larger.
Figure 14 A set of one-step LEI scans over the $5s^2 \, ^1S_0 - 5s \, ^3P_1$ transition in Sr in an acetylene–air flame. (a) The situation when light with four different laser irradiances (intensities) was scanned over the transition (12, 45, 175, and 550 kW cm$^{-2}$ as the four curves, from bottom to top, respectively) with a beam diameter of 2 mm. (b) The results from the simplest possible model of the situation that can reproduce the peak values (a two-level model of a Lorentzian absorption profile with some photoionization). (c) A situation corresponding to (a), with a 16-fold larger area (a beam diameter of 8 mm) but with the same irradiances, from which one can see clearly that the LEI one-step signal from Sr is composed of at least two parts. (d) A one-step spectrum (top curve) decomposed into the sum of two Lorentzian-shaped peaks (next two curves), with the bottom curve being the residual error of the decomposition. It can be concluded from a comparison between the widths of the curves in (a–d) that it is the broad peak that behaves as expected from theory. Hence, the narrow peak, which dominates the curves in (a), originates from “scattered” laser light. (Parts (a) and (c) are reproduced by permission of the Society of Applied Spectroscopy from O. Axner, S. Sjöström, *Applied Spectroscopy*, 44(5), 864–870 (1990).)

than with the 16 times smaller beam area (approximately 40–50% larger) and that a significant broadening of the lower parts of the peaks could be discerned. This gave some insight into the true physical origin of the LEI signal in this particular experiment. Analysis of the data showed that the LEI signal, in fact, can have several origins. It was found that each curve could be decomposed into a sum of two curves with significantly different widths, as is shown by Figure 14(d). The top experimental curve can be decomposed into a curve with broad shoulders and one narrow-band feature (next two curves). The curve with broad shoulders was found to follow rather well the predicted behavior of the LEI signal from an optically saturated system, but the narrow-band feature did not. This led to the conclusion that the signal with broad shoulders originates from atoms within the geometrically confined interaction region (referred to as the “true” interaction region), whereas the narrow-band peak has to be attributed to the signal from nonsaturated atoms in another part of the atomizer (i.e., outside the “true” interaction region) affected by what was referred to as “scattered laser light”. It was thus concluded that a significant (sometimes even a dominating) part of the signal from Sr can originate from “scattered laser
light” under a variety of conditions, as is exemplified by Figure 14(a).

A number of possible mechanisms for the existence of “scattered laser light” outside the “true” interaction region have been proposed: the light might be due to diffraction of laser light from an aperture positioned outside the flame; it might consist of fluorescence light from excited analyte atoms in the interaction region; or it might originate from light scattered from particles of flame molecules in the “true” interaction region of the flame. Despite attempts to understand the physical origin of this “scattered laser light”, no clear conclusion about its origin has yet been drawn. Furthermore, it has not been investigated to what extent this affects other elements detected by LEI. It is clear, however, that the influence of “scattered laser light” is smaller in two-step than in one-step experiments. This also explains why there has been a better agreement between measured and predicted signal strengths for two-step excitations than for one-step excitations in LEI spectrometry.

5.5.2 Noise

The most thorough description of the various sources of noise in LEI spectrometry has been given by Turk. He divides the various types of noise into two categories: multiplicative and additive noise. Multiplicative noise is defined as the noise that is proportional to the concentration of the analyte, and additive noise comes from the other components. This implies that as the concentration of the analyte decreases, the influence of the multiplicative noise decreases accordingly, so that only the additive noise determines the limit of detection. Multiplicative noise, on the other hand, can affect the precision.

5.5.2.1 Multiplicative Noise

Multiplicative noise can be due to fluctuations in the atomic population (affected by properties of the nebulizer/flame), the ionization yield (affected by properties of the laser), and the detection efficiency (affected by properties of the applied potential and the flame). Although pulse-to-pulse variation in the laser power can be substantial, it has been found that there is little correlation between the fluctuations of the LEI signal and those of the laser power. The main reason is attributed to optical saturation. Instead, in a simultaneous measurement of LEI and LIF in a flame, it was found that the correlation between the noise in the LEI and LIF signals was substantial. This provides evidence that the major source of multiplicative noise in this particular case resulted from fluctuations of the atomic population within the laser-irradiated volume.

5.5.2.2 Additive Noise

Additive noise can consist of electronic noise, thermal background ionization noise and laser-induced background ionization noise. Electronic noise can in turn consist of either Johnson noise in resistors or radiofrequency interferences emitted from pulsed lasers synchronous with the laser pulses. As was concluded by Turk, the electrodes, burner head and preamplifier seem to form an excellent antenna for radiofrequency interferences. Care in shielding and grounding the LEI instrumentation is therefore essential in LEI spectrometry. A comparison between the nonlaser-induced sources of noise for two flames (acetylene–air and hydrogen–air) and two different samples (synthetic drinking water with a few to some tens of ppm of EIEs and citrus leaves, diluted and digested to 10 mg mL$^{-1}$ with one to two orders of magnitude higher concentrations of EIE) were made by Turk.

It was found that although the root mean square of the electronic noise (no flame on) was 1.3 nA (unfiltered), the flames themselves contributed very little to this noise level. When drinking water was aspirated, however, the noise increased to approximately twice the value of the electronic noise (to 2.7 and 1.7 nA for the two flames, respectively). When the high-EIE samples were aspirated (citrus leaves), on the other hand, the noise increased considerably (to 23 and 6.2 nA, respectively). This shows that the dominating source of noise originates from the increased thermal ionization from EIE when samples with high concentrations of such elements are detected. In the absence of EIE most of the noise can be attributed to either electronic noise or flame current noise. Turk concluded furthermore that when the noise is dominated by flame noise, the noise magnitude is consistent with shot noise from the flame DC. When also considering the effect of signal averaging, the noise levels given above were found to be decreased significantly. Assuming a time constant of 1 s and exponential averaging over 10 Hz (as typical for Nd: YAG systems) the noise levels in the acetylene–air flame decreased to 0.45 and 3 nA (for the two samples, respectively), whereas the corresponding levels for a 300-Hz excimer system become 0.07 and 0.52 nA.

The relative importance of laser-induced background ionization noise is more difficult to assess because this type of noise depends on the amount of background signal generated by the laser (which normally is considered to be a type of interference). Irrespective of its origin (it can, for example, be due to wing excitation or multiphoton ionization of flame molecules), one can conclude, however, that this type of noise is particularly destructive for the LEI technique because in general it is affected by the fluctuations of the laser power (because wing excitation and multiphoton ionization are seldom optically saturated) as well as the atomic population in the flame, two entities that are known to carry a significant amount of noise.
5.5.3 Limits of Detection

5.5.3.1 Laser-enhanced Ionization in Flames

As was alluded to above, the most commonly used atomizer for LEI has been the flame. A rather large number of detection limits for LEI in flames have therefore been published throughout the years. The best LOD for each element have been collected in Table 5 (see references 72, 293, 306, 321, 322, 328, 336, 364, 366, 367, 370, 371, 383–385, 387, 388, 392, 396–399). The LOD have been stated as given in the original references. This implies that although some elements have LOD that are limited by the actual noise of the background (i.e. including background signals from contamination, etc.), some have been estimated from the instrumentation noise (i.e. obtained when detuning the laser(s) from resonance so as to avoid the influence of contamination). In addition, although most LOD have been given with an S/N of 3, measured over 1 s, some are taken under slightly different conditions (or under unspecified conditions).

As can be seen from Table 5, the majority of the LOD are in the picogram per milliliter region with a few even below, i.e. in the femtogram per milliliter range (In, Li, Na, Pb and Rb), and a limited number above, i.e. in the nanogram per milliliter range (As, Eu, Mo, Si and W).

The best LOD correspond fairly well to the realistically estimated best LOD for the LEI technique. Turk calculated the best possible LOD for two different

a E = excimer-pumped dye laser system; N = nitrogen-pumped dye laser system; Y = Nd: YAG-pumped dye laser system; F = flashlamp-pumped dye laser system.
b AA = acetylene–air; AN = acetylene–nitrous oxide; PBA = propane–butane–air; HA = hydrogen–air.
c Additional references with LOD that are within a factor of three from the best. These works in general do not use the same type of laser, wavelength or flame as that specified.
situations. Under the somewhat unrealistic condition that the detection power should be limited by the shot noise of the thermal ionization, he found that the LOD should be 3 fg mL$^{-1}$. This is far below any experimentally found LOD. When basing the calculation upon a more realistic situation (assuming that the detection power is limited by the actually measured noise values), the LOD was found to be of the order of 0.1 pg mL$^{-1}$. As can be seen from Table 5, there are a few elements that have their LOD within one order of magnitude from this estimated optimum LOD (primarily In, Li, Na, Pb and Rb). This indicates that there is still room for improvements for most of the detected elements for LEI in flames.

5.5.3.2 Laser-enhanced Ionization in Plasmas

The detection power of laser-based ionization techniques has not been improved as much as for conventional techniques when going from flames to ICPs, for reasons given in the instrumentation section (section 5.4).

The first attempts to combine an ICP with a laser-based ionization technique were made by Turk and Watters. In order to circumvent these problems, the authors used an extended plasma torch and placed two charge-collecting electrodes 19 cm above the load coil (in the tail flame, so as to benefit from the higher neutral atom fraction that exists in the cooler part of the plasma and to minimize the influence of radiofrequency interferences). The detection powers were clearly inferior to those previously attained by the LEI technique in flames (e.g. LOD for Cu of 7 µg mL$^{-1}$).

In order to increase the detection power of LEI in an ICP and to perform measurements in the analytically most preferable position in the plasma, Turk et al. power-modulated an ICP by temporarily turning the plasma off (reducing the influence of radiofrequency interferences and decreasing the plasma background ion/electron concentrations). Ionization measurements were made 1.4 ms after complete interruption of plasma. LOD in the nanogram per milliliter range were achieved: for Fe and Ga, 80 and 20 ng mL$^{-1}$, respectively. It was concluded that the primary mode of ionization of the laser-excited atoms was photoionization rather than collisional ionization (i.e. more in-line with RIS).

Other atomizers have been investigated for possible application in LEI spectrometry, but with limited success. The microwave-induced plasma, for example, has been investigated by Seltzer and Green. Another example is the use of an atmospheric pressure micro-arc plasma with LEI, which was investigated by Churchwell et al.

5.5.3.3 Laser-enhanced Ionization in Graphite Furnaces

As was alluded to above (in section 5.4), a variety of experimental configurations of furnaces and probes have been scrutinized for LEI in a GF. The common experiences are that the sensitivity is not as large as expected and that signal fluctuations are considerable.

For example, already the first measurements indicate that there is a somewhat lower collisional ionization rate (or yield) in the furnace than in the flame. One such indication was the finding by Gonchakov et al. that the LEI signal from two-step excitation of Na could be increased significantly (by a factor of 20–40) by actively photoionizing the atoms with infrared light from a Nd : YAG laser. Magnusson et al. compared signal strengths (on a sensitivity basis) from flame LEI and LEI in a GF and concluded that the Na signal from the latter was smaller than expected and that from Mg was larger. The smaller Na signal strength was attributed to a lower collisional ionization rate in the furnace than in the flame, whereas the larger Mg signal was explained partly as photoionization.

Moreover, many authors have noticed that there was always a background signal, fully resonant with the species detected, as soon as any liquid was injected into the furnace (corresponding to that from a few picograms of analyte). Magnusson et al. showed explicitly that there were no background signals when the furnace was heated empty (with the lasers on) and concluded that the background signal originates from contamination.

Many LOD for LEI in a GF are in the picogram range. Magnusson et al. quoted contamination-limited LOD that are in the picogram range (Co, 5 pg; Cr, 5 pg; Mg, 1 pg; Mn, 1 pg; Na, 5 pg; Ni, 7 pg; Pb, 0.5 pg). The contamination-free LOD for Mg and Na were estimated to be 0.03 and 0.5 pg, respectively (obtained from measurements when no sample was injected into the furnace). Gonchakov et al. had previously estimated the LOD for Na in the absence of contamination to be in the low femtogram range. Moreover, the LOD for Mn and Sr measured with the T-furnace by Magnusson et al. were assessed to be 1 and 2 pg, respectively. Detection of Yb and In, using two-step excitation with the probe above the dosing hole, yielded LOD of 1 pg and 0.8 fg, respectively.

Butcher et al., finally, found that the limiting noise for their LEI system in a modern HGA-500 furnace with a moveable probe was furnace noise and thermionic emission. LOD were established for a number of elements (Tl, 2 pg; In, 0.7 pg; Pb, 60 pg; Li, 1 pg; Mg, 10 pg; Mn, 30 pg; Fe, 50 pg; the LOD were determined on-line for all elements except Li and Mg). In agreement with previous authors, they found that the precision was poor (between 12 and 16%). They attributed this to poor precision of the manual pipetting, but gave no conclusive evidence as to whether this originated from any parts of the LEI or GF instrumentation (e.g. fluctuations in the charge-collection efficiency) as had been suggested earlier.
It can be concluded that the furnace does not bring
the same advantages for the LEI technique as it does for
the LIF/LEAFS technique, for the reasons described in
section 5.4.2.3.

5.5.3.4 Laser-enhanced Ionization in Rod–Flame Systems
As was alluded to above, an alternative means of
atomization is the rod–flame system developed by
Chekalin et al.\(^\text{(333,335–338)}\) The most significant advantages
with this system come from its ability to handle samples
with high concentrations of concomitant elements and for
analyses of solid materials. It was, for example, concluded
that the background signal from the matrix decreased by
over two orders of magnitude when samples in solid form
were analyzed in comparison with samples in liquid form.
This allowed for detection limits in solid samples down
to the picogram per gram level. LOD for the rod–flame
system are generally low (Au, 200 fg;\(^\text{(336)}\) Co, 1 pg;\(^\text{(338)}\) Cr, 2 pg;\(^\text{(338)}\) Cu, 2 pg;\(^\text{(335,336)}\) In, 4 fg;\(^\text{(335,336)}\) Mn, 3 pg;\(^\text{(338)}\) Na, 2 fg;\(^\text{(336)}\) Ni, 800 fg).\(^\text{(338)}\)

The rod–flame instrumentation has been used for
detection of: In in CdHgTe solutions,\(^\text{(335,336)}\) Au in
AgNO\(_3\,\text{333}\), Cu in Ge,\(^\text{(335,336)}\) Na and Cu in orthophosphoric
acid,\(^\text{(333)}\) Li, K, Na, Sb, Cu and Ag in phosphoric
acid, acetone and isopropanol,\(^\text{(337)}\) Ni, Co, Cr and Mn in
fiber-optic fluoride materials,\(^\text{(337)}\) and Cr, Co, Mn and Ni
in NH\(_4\)F and NaF.\(^\text{(338)}\)

5.5.3.5 Laser-enhanced Ionization in Graphite Furnace–
Flame Systems
Two-step excitation from a pulsed
Nd : YAG-pumped dye laser system was used to detect
Mg, Tl and In in the previously described combined
GF–flame system developed by Smith et al.\(^\text{(339)}\) After
optimization of various parameters (e.g. carrier gas flow),
the LOD for these elements could be assessed as 1,
120 and 260 fg, respectively.

Riter et al. determined experimentally the vapor-
ization, transport, atomization, probing, and detection
efficiencies of Mg atoms in an LEI system in which a GF
was coupled to a miniature flame.\(^\text{(340)}\) The authors esti-
mated the overall efficiency of the system to be 0.0025%.
The experimental LOD was 20 pg. The LOD for Mg was
estimated to be 6 fg in the absence of the blank and
after a reduction of radiofrequency noise.\(^\text{(340)}\) The same
group has subsequently used an LEI–GF–flame system
for the determination of Pb in whole blood. An LOD of
90 pg mL\(^{-1}\) (0.9 pg absolute) was found for lead in whole
blood.\(^\text{(400)}\)

5.5.3.6 Laser-enhanced Ionization in Cells
Mercury has been studied by ionization techniques directly in a
cell.\(^\text{(378,270,341–346)}\) Cleveneger et al. studied the temporal
behavior of the LEI signal of Hg in a quartz cell
under low buffer gas pressure. Using fast electronics
and a short laser pulse, it was possible to distinguish,
in one single time-resolved ionization waveform, the
nonselective photoinization component of the signal
from that due to collisional ionization from selected
levels. Experimental results were shown to agree with
those obtained by computer simulations, and optimal
conditions for deconvolution of the two components were
assessed.\(^\text{(343)}\) A spectroscopic study of Hg Rydberg states
(\(n = 10–42\) ) was also made. Broadening and splitting
caused by the influence of Stark effects and of increasing
buffer gas pressure were observed. The optimal operating
conditions, in terms of pressure and applied high voltage,
for obtaining the best sensitivity and LOD by analytical
LEI spectroscopy were identified.\(^\text{(344)}\)

A new method for the detection of Hg atoms in an
inert gas atmosphere by LEI, based on the avalanche
amplification of the signal resulting from the ionization
from a selected Rydberg level reached by a three-step
laser excitation of mercury vapor in a simple quartz
cell, was developed by Cleveneger et al.\(^\text{(345)}\) An avalanche
amplification effect was found when Ar and P-10 gases
were used at atmospheric pressure. The authors estimate
that an LOD of 15 Hg atoms per laser pulse in the
interaction region is achievable under amplifier noise-
limited conditions.\(^\text{(345)}\) A comparison of various means to
detect Hg (including laser-based techniques) is given by
Clevenger et al.\(^\text{(346)}\)

5.5.4 Interferences
Interferences are phenomena that adversely affect the
performance of a technique. There are two types of
interferences in LEI spectrometry: space-charge and
laser-induced interferences. Although space-charge inter-
ferences are exclusively associated with EIEs and affect
the charge-collection process, spectral interferences can
originate from either matrix elements (to a large extent
EIEs) or flame native molecules and therefore affect
primarily the excitation–ionization process.

5.5.4.1 Space-charge Interferences
Space-charge interferences originate from the fact that (for a given
potential applied across the flame) the electrical field
distribution depends strongly on the thermal ionization
rate.\(^\text{(307,316,401)}\)

As was described in the instrumentation section
(section 5.4), applying a potential across a weakly ionized
plasma (as LEI atomizers can be characterized as) gives
rise to two distinctly different regions: the sheath, in which
there is a finite electrical field; and a fieldless region (close
to the anode). Only charges created in the sheath
will contribute to the signal. Because the extent of the sheath
depends on the amount of thermally produced charges,
the active interaction volume (i.e. the volume in the flame
in which the laser beam overlaps with a nonzero external
field) will decrease (i.e. shrink towards the cathode) with increasing amount of EIEs (because EIEs contribute significantly to the thermal ionization in the flame). Hence, when samples with high concentrations of EIEs are investigated, only the charges created close to the cathode will contribute to the signal. Moreover, because normally only the electronic part of the signal is being measured, the creation of a pair of charges close to the cathode (from which the electronic part of the total LEI signal is larger than the ionic part) will give rise to a larger LEI signal than if the charges were created further away from the cathode. This implies that the laser beam preferably should be directed close to (i.e. just below) the immersed electrode in order to have the highest immunity to EIEs and yield the highest signal. This also explains why the externally positioned cathodes are not capable of handling samples with high concentrations of EIEs (they have their cathode sheath across a cold region in which no free atoms exist).

Although the influence of space-charge interference can be reduced by a proper choice of electrode and probe volume, this type of interference is a considerable limitation to the applicability of the LEI technique.

A flow injection system has been interfaced to an LEI apparatus to handle samples with high concentrations of EIEs by Wang et al. With the use of the flow injection/laser-enhanced ionization (FI/LEI) apparatus, the electrical interference induced by the matrix could be effectively diminished. It was found that the FI/LEI technique is capable of detecting indium in a solution containing an Na matrix of more than 40 ppm ($\mu$g mL$^{-1}$), which was about 20 times higher than what the conventional LEI apparatus could tolerate. The authors state that it also has a much larger LDR than conventional LEI. Additional advantages are good reproducibility and a rapid sampling rate.

5.5.4.2 Spectral Interferences Spectral interferences can be separated into the following categories: ionization of native flame molecules; matrix spectral interferences (i.e. wing excitations or direct overlap between the spectral line of the analyte species with those of the matrix elements); and ionization of matrix elements by laser ASE.

Although there are several molecular species present in a flame, there are only a few that give rise to ionization signals. The NO molecule is the flame species that gives rise to the most severe flame background signals. With its strongest bandhead around 227 nm, and with others at around 237 and 248 (etc.) nm, it is a source of background signals primarily in the UV region. It has been found, however, that the ionization signal from NO is due to a two-photon excitation, in which case the signals can be held at moderate levels by avoiding focusing too strongly in the flame. Most other flame molecules that contribute to background signals in fluorescence or emission techniques, e.g. OH, have a larger tendency to dissociate than to ionize when being excited under the conditions typically prevailing in LEI spectroscopy, so they do not contribute to the LEI background signal.

Matrix spectral interferences, on the other hand, are in general a more severe problem in LEI spectrometry. Direct overlaps between a transition in an analyte and that of a matrix are rather scarce. Wing excitations of transitions in matrix elements, on the other hand, are much more frequent. It has been found that wing excitations of ubiquitous alkali and alkaline earth elements give rise to substantial background signals in LEI spectrometry. One such example is seen in Figure 15, which shows the LEI signal from a 20$\mu$g mL$^{-1}$ Na solution in the vicinity of the 3s–3p transition. As can be seen, wing excitations exist even several nanometers from the transition wavelength.

In addition, alkali elements often have quite a low ionization limit. When such an element is exposed to laser light with wavelengths below their threshold wavelength for direct photoionization from the ground state, a structureless LEI background signal appears. The threshold wavelengths for direct photoionization for Li, Na, K, Rb and Cs are 230, 241, 286, 297 and 318 nm, respectively. Hence, whenever UV light is used for investigating samples with large amounts of alkali matrix elements, a significant and unstructured LEI background signal will appear. As with all background signals, this will add to the existing noise in the system, thus reducing the detection power of the LEI technique.

A thorough study of background signals (direct overlap, wing excitations and photoionization) from Na in the

Figure 15 One-step LEI signal from 20$\mu$g mL$^{-1}$ of Na in the vicinity of the 3s–3p transition. (Reproduced by permission of John Wiley & Sons, from G.C. Turk, in Laser-enhanced Ionization Spectrometry, eds. J. Travis, G. Turk, 161–211, 1996.)
The entire 200–450 nm region was conducted by Axner et al.\(^{(577)}\). They found that even when the laser was detuned as much as possible from the discrete transitions, there was an Na signal from wing excitation that will create a background signal whenever samples with large amounts of Na are detected, as is shown in Figure 16. It was found that the background signal originates mainly from direct photoionization from the ground state below 240 nm; excitation to a number of closely spaced Rydberg levels gives rise to a strongly structured background signal in the 240–260 nm region; direct overlap or wing excitations of the strong 3s–4p, 3s–5p, 3s–6p and 3s–7p transitions dominate between 260 and 360 nm, whereas photoionization of thermally excited 3p atoms predominantly takes place slightly below 420 nm.

Moreover, a part of the light emitted from a dye laser consists of ASE. This broad-band light, which occurs within the tuning curve of the dye used, is usually of much lower power than the laser light but nevertheless can be responsible for excitation of concomitant elements. Because the amount of ASE emitted from a laser is not strongly dependent on the laser light wavelength (except at the edges of the tuning curves where it increases), it gives rise to a rather wavelength-independent background signal.

5.5.5 Selectivity

It has been corroborated frequently that LEI is a technique that has a high sensitivity (implying that the number of charges created per photon absorbed is high, in some cases close to unity). This is especially the case for the alkali elements because they have a rather low ionization potential and are easily atomized in a flame. This is, however, also the Achilles heel of the LEI technique. As was shown for Na above, all alkali elements will give rise to various types of spectral interferences (wing excitations or photoionization from lower-lying states). Any analyte to be detected in a matrix of alkali element therefore has to be detected on top of a background signal. The high sensitivity of the alkali elements thus reduces the detection power of other analytes and reduces the selectivity of the LEI technique. The selectivity of LEI therefore has been found to be lower than that of the LIF/LEAFS technique. This is an unrelenting consequence of the fact that LEI is a technique in which the selectivity provided by the laser source is limited by the amount of resolution it can provide when coupled with an undiscriminating charge-collecting detector.

5.5.5.1 Means to Improve Selectivity – Proper Choice of Laser Irradiance

One possible remedy to the aforementioned problem of interferences and limited selectivity is to excite the analyte atoms with as low an irradiance as possible in order to avoid excess optical saturation of the transitions of the analyte (and minimize the effect of background signals from matrix elements).

An example is shown in Figure 17. So far, the most severe spectral interference encountered for LEI spectrometry occurs when Mg is to be detected in the presence of Na. The reason is that Mg has its only practically accessible transition (3s\(^2\)–3s 3p) at 285.21 nm whereas Na has one of its strongest transitions (3s–5p) at 285.28 nm, which is only 0.07 nm away. It is therefore clear that significant wing excitations of Na atoms will occur when the laser is tuned to the Mg resonance. Figure 17(a) shows the situation for one-step excitation of 10 ng mL\(^{-1}\) Mg in a matrix of 10 times more Na, i.e. 100 ng mL\(^{-1}\), using a laser irradiance of 25 kW cm\(^{-2}\). As can be seen from Figure 17(a), there is a spectral interference at the wavelength of the Mg transition already for this rather moderate amount of Na matrix under these conditions.

One way to increase the selectivity is to adjust the laser irradiance so as to avoid excess optical saturation of the Mg transition. Figure 17(b) shows the situation when the

---

**Figure 16** Experimentally measured (intensity- and concentration-normalized) LEI signal strengths for Na versus wavelength. The open and solid markers represent individual measurements done by various dyes in the dye laser: (a) Coumarin 47; (b) Coumarin 102; (c) Coumarin 307; (d) Coumarin 153; (e) Rhodamine 6G; (f) DPS. The predicted LEI signal from direct photoionization from the ground state (below 240 nm) is indicated by solid curve (g). Various discrete resonance transitions are indicated with the solid and dashed line (h) (the peak at around 185 nm corresponds to the 3s–5p transition). The lowest contribution from wing excitations of the 3s–np transitions in each wavelength region is indicated by solid line (i). The predicted contribution from photoionization of the thermally populated 3p state is indicated by the solid curve (j). (Reproduced by permission of the Society of Applied Spectroscopy from O. Axner, M. Norberg, H. Rubinshtein-Dunlop, *Applied Spectroscopy*, 44(7), 1124–1133 (1990).)
laser irradiance has been attenuated to 0.5 kW cm\(^{-2}\). The interference from Na at the Mg transition has decreased considerably.

The increase in selectivity is not sufficient, however, when samples with higher Na concentrations are to be analyzed. Figure 17(c) shows the situation when the Na concentration has been increased by one order of magnitude (i.e. to 1 µg mL\(^{-1}\)).

5.5.5.2 Means to Improve Selectivity – Use of Two-step Excitations

By illuminating the atoms from the example above also with 470.30-nm light, in order to excite the Mg atoms closer to the ionization limit by a two-step process (3s\(^2\)–3s3p–3s5d), the Mg signal will be increased and thereby also the selectivity. In this particular case, the signal enhancement was about 300, as is shown in Figure 17(d), and thus virtually all of the Na interference at the Mg transition has been eliminated.

However, although an optimization of the working conditions (regarding laser irradiance, laser beam area, etc.) and the use of two-step excitation can increase the selectivity considerably, they cannot completely eliminate the spectral interferences. This is illustrated in Figure 18, where the influence of wing excitation on the detection of Ni in an Na matrix is displayed. Nickel atoms are excited by a two-step excitation (at 300.3 and 561.5 nm) for best sensitivity. The second-step laser is scanned across the second-step excitation in Ni for two water solutions containing 100 ng Ni mL\(^{-1}\) with and without the presence of 100 µg Na mL\(^{-1}\) of matrix. A background signal is clearly visible for the sample containing the Na matrix. In this case, the background signal originates...
from a wing excitation for the 3p–4d transition with a central wavelength of 568.8 nm. Although the presence of 100 µg Na mL\(^{-1}\) does not influence the charge collection efficiency (the Ni peaks are virtually the same), it considerably decreases the S/N ratio.

5.5.6 Applications

The LEI technique has been used for a variety of applications, both analytical as well as diagnostic. A thorough review of the analytical applications of LEI has been given by Green.\(^{317}\) A common analytical application is the assessment of traces in standard reference samples. Another is to determine the metal application is the assessment of traces in standard detector for Raman light;\(^{\text{404}}\) corresponds to that of the first excitation step. One and narrow-band detector of light whose wavelength from a laser system. This system then acts as a sensitive and narrow-band detector of light whose wavelength is measured by the same authors in another work.\(^{375}\) The ionization efficiency of Na atoms in an acetylene–air flame (defined as the probability than an excited atom ionizes rather than returning to the ground state) was measured by the same authors in another work.\(^{90}\) The ionization yield (defined as the fraction of atoms in the ionization rates,\(^{417}\) ionization rates,\(^{418}\) flame temperatures\(^{418,419}\) and dynamic Stark effects (i.e. effects on the energy levels induced by the laser light).\(^{109}\)

A demonstration of the applicability of a delayed two-step LEI technique for measurement of the lifetimes of metastable states (in Pb and Tl) in an acetylene–air flame was first demonstrated by Omenetto et al.\(^{81}\) Axner et al. made a more thorough study of nine different

5.6 Diagnostic Capabilities

The high sensitivity of the LEI technique makes it useful as a diagnostic tool. A number of various entities and phenomena have been investigated by the LEI technique throughout the years and a few examples in this field follow.

5.6.1 Laser-enhanced Ionization in Flames

Studies concerned with the excitation and ionization processes (including energy pooling effects, charge exchange rates, etc.) in a variety of atomic reservoirs have been performed by a number of authors.\(^{270,357,360–362,414}\) For example, Turk developed a methodology that can determine where within a flame LEI actually takes place.\(^{314a,414b}\) He found that spatial control of the flame volume sampled by the ionization detection electrodes could be obtained by varying the applied voltage across the flame. This procedure was used to observe anomalous contributions to LEI caused by scattering or fluorescence from the laser beam to other regions in the flame. Axner and Berglind demonstrated that the LEI technique can be used to measure the electrical field distribution in a flame by monitoring the Stark-splitting Rydberg states that are exposed by the electrical field.\(^{375}\) The

Figure 18 Two-step LEI spectra for 10 ng mL\(^{-1}\) Ni in pure deionized water and in a matrix of 100 µg/mL Na as the lower and upper curves, respectively. The first-step laser is fixed on the 300.249 nm transition in Ni and the second-step laser is scanned over the second-step excitation at around 561.5 nm. metastable states under a variety of conditions in an acetylene–air flame.\(^{(82)}\) A few such examples are given in Figure 19. They concluded, among other things, that metastable states that are forbidden to decay to lower states because of a parity violation generally have longer lifetimes (85 ns–3.1\(\mu\)s) than those that are forbidden to decay by violation of spin conservation (5–33 ns).\(^{(82)}\) They also showed that the lifetime of a metastable state depends strongly on the local stoichiometry in the interaction volume (the lifetime of a specific metastable state in Au was found to range between 600 ns and 8.8 \(\mu\)s, depending on the local stoichiometry), which led to the finding that the LEI technique could be used to map the local stoichiometry in an acetylene–air flame.

flame by monitoring the lifetimes of atomic metastable states.\(^{82-84}\)

The two-step LEI technique has also been used to measure flame flow velocities or gas velocities in a shock tube.\(^{420-423}\) One laser system is used to deplete the density of neutral atoms located in the middle while another is used to probe the time development of this depleted region. The fluorescence dip technique, finally, has been used to study laser-enhanced emission processes.\(^{268}\)

5.6.2 Laser-enhanced Ionization in Plasma

Because ICP provides a rather different ionization environment than do flames, it is not clear, a priori, how excited atoms ionize in this type of atomizer. Laser power studies were therefore made on several elements (Cu, Na, Fe and Mn) to investigate the ionization mechanisms of the excited atoms.\(^{323}\) However, the results were not fully conclusive. Both Fe and Mn, which were excited to states whose energy is slightly above half of the ionization energy, showed a linear laser power dependence. Assuming that the optical transition was saturated at the intensities used, this indicates that the major ionization route is photoionization for these elements. Copper was found to be excited in two-photon transitions to states close to the ionization limit from which ionization is assumed to proceed, with no further involvement of any light-induced process. For Na (excited to the 3p state), collisional ionization was the most probable ionization mechanism.

Laser-induced ionization in an ICP has also been performed by Turk et al. in order to measure the ionization yield and the fate of the laser-produced Sr ions in the ICP. Neutral Sr atoms were excited and photoionized by one laser system, while the number of Sr ions produced was monitored by another laser system (using the LIF technique).\(^{327}\) By inducing a delay between the two ionizing and probing laser systems, it was found, among other things, that the recombination time constant of Sr ions in the ICP was 15.5 µs (but this decreased with increasing numbers of EIEs).

In another study concerned with the fate of ions in an ICP, Yu et al. found that the laser-induced enhancement of Sr\(^{+}\) ions in a modified inductively coupled plasma mass spectrometer (ICPMS) instrument lasted for approximately 0.25 ms and peaked 0.2 ms after the laser pulse at a value of 11% relative to the Sr\(^{+}\) ion signal due to the plasma ionization alone. The authors found that the laser-induced signal was limited by the high degree of direct plasma ionization and ion–electron recombination of laser-produced ions.\(^{325}\)

With the use of a simplified model of the magnesium atom, several possible approaches to the measurement of charge exchange rates between Mg and Ar in the ICP have been developed.\(^{414}\) Two of the approaches, which used pulsed dye lasers to populate the Mg(II) levels that are close to resonance for charge exchange, were tested experimentally. The experiments yielded an effective rate constant for the transfer of charge from Mg\(^{2+}\) to Ar of 1.1 \times 10^8 s\(^{-1}\). This value is a factor of 50 lower than previously published estimates.\(^{414}\)

A commercial ICPMS instrument, modified for use with a flame rather than an ICP, was used to sample and detect the LEI ions. Using double-resonance LEI with pulsed dye lasers, an Na\(^{+}\) signal that was 350 times larger than that induced by thermal ionization could be achieved. Using a 5-mm laser beam diameter, the LEI signal ion pulse was found to last for 0.53 ms. Spatial studies, in which the position of the laser beam relative to the mass spectrometer sampler cone was varied, demonstrated that the ions produced by LEI travel with the flame velocity into the mass spectrometer, with no significant losses due to recombination from as far as 13 mm from the interface.\(^{424}\)

5.7 Conclusions and Outlook for Laser-enhanced Ionization

It is clear that LEI is a highly sensitive laser-based spectroscopic technique that benefits from using a simple flame as atomizer (which allows for an uncomplicated sample introduction). LOD in the picogram per milliliter range have been obtained for a large number of elements (and with a few LOD even below this range). The most significant drawback of the technique is its sensitivity to EIEs. When samples with considerable numbers of EIEs are analyzed, significant background effects that limit the detection power of the analyte appear. This has limited the use of LEI primarily to situations when samples with uncomplicated matrices are to be analyzed. The technique has a great potential for diagnostics (e.g. of atomizer-specific physical and chemical processes) as well as for basic studies.

5.8 Resonance Ionization Spectrometry

5.8.1 Historical Development of Resonance Ionization Spectrometry

RIS was historically developed as a means of probing excited (metastable)-state populations in He as part of a study of the intricate interplay between various types of energy transfer processes in noble gas systems in the middle of the 1970s.\(^{119}\) At that time it was conceived that photoionization could provide a more unambiguous probing of the excited-state populations than emission because the emission processes from metastable states in noble gas atoms are indirect. It was soon found, however, that the real importance of the photoionization approach
was that it could provide a quantum-state selectivity if a tunable pulsed laser were used to first excite the metastable atom to another excited state, after which photoionization could proceed by absorption of a second photon from the same laser. The use of an intermediate state ensured that the ionization process could take place only if the laser wavelength was resonant with an existing transition in the atoms, which thus gave the process its name: RIS.\(^{(19)}\)

5.8.2 Early Acquaintances for Resonance Ionization Spectrometry with the Field of Analytical Applications – Single Atom Detection 

It was soon recognized that the RIS technique had an extraordinary potential for analytical applications by tuning the laser light to transitions originating from the highly populated ground state. It was even prophesied early on that SAD capabilities were within reach. The SAD capability of RIS was demonstrated by Hurst et al. in 1977 in a proportional counter detecting individual Cs atoms.\(^{(9,10)}\) Since then the field developed rapidly, with the aim of meeting the various requirements of an analytical technique.\(^{(10,11,19,41,271–285)}\) The RIS technique was first applied to species like alkali atoms, whose ionization limit was so low that the RIS process was feasible with the laser systems available at that time. As tunable laser systems became more advanced and more prevalent, however, RIS was also applied to other types of species.\(^{(9–11,19,41,271–285)}\)

5.8.3 Estimated Analytical Properties of Resonance Ionization Spectrometry 

The greatest advantage of RIS is undoubtedly the unmatched combination of high sensitivity (a high ionization yield for the laser-illuminated atoms) and high selectivity. It has been found, for example, that almost 100% of the illuminated atoms can be ionized. The selectivity (calculated as a product of the estimated selectivity of each excitation step) was estimated to be of the order of \(10^9–10^{12}\) under quite general conditions (e.g. from RIS using two resonant excitation steps followed by photoionization from the uppermost laser-connected level), and even higher under more favorable conditions. In addition, if the laser-produced ions were detected by a mass spectrometer (most often a time-of-flight mass spectrometer for pulsed excitations and a quadrupole mass spectrometer for continuous-wave excitations), the selectivity could be even larger. The technique is then often referred to as resonance ionization mass spectrometry (RIMS). This high selectivity gives the resonance ionization spectrometry/resonance ionization mass spectrometry (RIS/RIMS) technique good applicability to isotopic selective assessments, an application area in which most other optical techniques are not as amenable owing to the increased transition widths in finite-pressure atomizers (collisionally broadened). This extraordinary selectivity has truly given the RIS/RIMS technique extraordinary promise for analytical applications.

5.8.4 Practical Limitations of Resonance Ionization Spectrometry/Resonance Ionization Mass Spectrometry 

Reality showed that not all of the expected properties of RIS/RIMS could be realized readily as first anticipated. The main limitation of the technique is a poor temporal and/or spatial overlap between a thermally atomized sample and the interaction volume. This is particularly evident when pulsed laser sources are used for excitation (which was the prevalent situation for the first years, mainly dictated by the availability of UV laser light) together with thermal atomization. For example, the spatial and temporal overlap of a thermal atomic beam and the light from a pulsed laser system is of the order of \(10^{-5}\) using a 25-Hz repetition rate laser (and typical values for other parameters). Means to improve on this consist mainly of using a high-duty-cycle laser system (i.e. atomic-vapor-pumped dye laser systems\(^{(425)}\) or continuous-wave lasers, either ion-laser-pumped dye laser systems\(^{(426)}\) or, lately, diode laser systems\(^{(427)}\) or pulsed atomization sources (e.g. laser ablation\(^{(428,429)}\) and sputter-initiated atomization\(^{(430)}\)).\(^{(431)}\) The use of a 6.5-kHz atomic-vapor-pumped dye laser system instead of a conventional pulse laser with a 25-Hz repetition rate, for example, increases the spatial and temporal overlap by two or three orders of magnitude to a few tenths of a percent.\(^{(432)}\)

5.8.5 Practical Applicability of Resonance Ionization Spectrometry/Resonance Ionization Mass Spectrometry 

An assessment of the analytical capabilities of the RIS/RIMS technique can most easily be performed by studying the practical applicability of the technique. The RIS/RIMS technique has been used for a variety of applications in both the basic and applied sciences throughout the years.

5.8.5.1 Basic Studies with Resonance Ionization Spectrometry/Resonance Ionization Mass Spectrometry 

The basic studies have often been concerned with measurements of atomic physics entities, e.g. hyperfine structures,\(^{(435)}\) ionization potentials,\(^{(434)}\) photoionization and continuum structure\(^{(435,436)}\) (including studies of negative ions\(^{(437,438)}\) ), and for high-precision measurements,\(^{(439)}\) etc. but also for studies of basic quantum phenomena,\(^{(440)}\) e.g. dynamic Stark shift\(^{(441,442)}\) and population dynamics.\(^{(443)}\)
5.8.5.2 Analytical Applications of Resonance Ionization Spectrometry/Resonance Ionization Mass Spectrometry

The analytical applications of RIS/RIMS were originally devoted to studies of atomic species but molecular species have been assessed also during latter years. The most recent activity within the field of analytical atomic spectrometry has been on isotopic issues. For example, double-resonance RIMS using single-frequency continuous-wave dye lasers has demonstrated detection limits in the attogram range for $^{90}\text{Sr}$ and an optical isotope selectivity above $10^9$ in measurements of $^{90}\text{Sr}$.

One particular problem of using RIS/RIMS for isotope determinations, however, is that various isotopes can have different sets of (i.e. different numbers of) hyperfine components of a given atomic level and thereby different degeneracy factors of the laser-connected states. Because the ionization rate depends on details of the level structure of the atoms under study, the ionization fraction will vary between various isotopes. This is often referred to as the odd–even effect because isotopes with an even mass number generally lack nuclear spin ($I = 0$) and thereby hyperfine structure, whereas isotopes with odd mass number have a finite nuclear spin (i.e. $I \neq 0$) and show hyperfine structure. This effect is now understood (theoretical predictions have been verified by experiments) but the effect has to be taken into account properly when analyzing experimental data. There are several ways to reduce the odd–even effect in practical RIS/RIMS measurements, e.g. reducing the resonance laser intensity well below saturation, increasing the ionization intensity to full saturation so that all isotopes are ionized, or working with depolarized laser light or short pulses.

One of the most important uses of RIMS applies its ability to detect low concentrations of long-lived radioisotopes, prompted by the fact that radiometry faces various problems in the detection of some of the most important and hazardous radioisotopes. For example, for very long-lived $\alpha$- and $\beta$-emitters (e.g. $^{239}\text{Pu}$ with $t_{1/2} = 2.41 \times 10^4$ years and $^{99m}\text{Tc}$ with $t_{1/2} = 2.1 \times 10^5$ years), the measuring time is very long using radiometric methods. In addition, detection limits are impaired by the background. Some isotopes cannot be distinguished by $\alpha$-spectroscopy owing to the very similar energies of the $\alpha$-lines (e.g. the pairs $^{239}\text{Pu}/^{240}\text{Pu}$ and $^{238}\text{Pu}/^{241}\text{Am}$). Furthermore, because the continuous energy spectra of the $\beta$-emitters $^{89}\text{Sr}$ and $^{90}\text{Sr}$ overlap, they cannot be measured separately by $\beta$-spectroscopy. $^{90}\text{Sr}$ ($t_{1/2} = 28.5$ years) therefore often has to be detected via the daughter isotope $^{90}\text{Y}$, which includes a waiting time of about 10–14 days. This situation has justified the RIS/RIMS technique to seek applications in the detection of long-lived radioisotopes. Erdmann et al., for example, demonstrated detection of $^{239}\text{Pu}$ with LOD of only $10^6$ atoms using RIMS.

Isotopic $\text{Pu}$ compositions could be determined with sufficient accuracy to assess the isotopic composition of $\text{Pu}$ in soil from the Chernobyl area. Passler used RIMS to detect long-lived radioisotopes like $\text{Pu}$, $\text{Tc}$, and $^{89,90}\text{Sr}$. The LOD of $^{89}\text{Sr}$ and $^{90}\text{Sr}$ were $5 \times 10^7$ and $3 \times 10^6$ atoms, respectively.

RIS/RIMS has also been used for precise determination of $\text{Ca}$ isotope ratios, primarily $^{41}\text{Ca}$ for purposes of geological and anthropological dating. Other uses of techniques capable of a precise assessment of widely different $\text{Ca}$ isotope ratios include the evaluation of exposure histories of extraterrestrial materials, measurements of ratios of the minor stable isotopes in meteorite inclusions for tests of nucleosynthetic models, and investigations of isotope traces in medical studies. The analytical requirements for these applications vary widely, but for dating measurements with $^{41}\text{Ca}$ they include, among other things, an isotopic selectivity of $10^{15}$. In order to accomplish this, and therefore with the objective of finding the most optimal excitation schemes for precise determination of $\text{Ca}$ isotope ratios, a series of studies concerned with isotope shifts and hyperfine structure, as well as line shapes and optical selectivity issues in $\text{Ca}$, have recently been performed.

Although many laser sources produce light with an extremely narrow bandwidth, the combination of small optical isotope shifts and finite broadening mechanisms (Doppler shifts and natural broadening) restricts the isotopic selectivity of the RIS/RIMS technique in certain applications. As a means to improve on this, collinear RIS/RIMS on accelerated atoms has been performed. The use of accelerated atoms eliminates Doppler broadening and enlarges the isotope shifts, whereas the collinear approach increases the interaction volume. After a long series of methodology improvements, LOD of $3 \times 10^6$ atoms of $^{90}\text{Sr}$ (corresponding to an activity of 2 mBq) in the presence of up to $10^7$ atoms of stable $^{88}\text{Sr}$ could be achieved.

The combination of pulsed atomization and RIS/RIMS not only provides a higher temporal and spatial overlap between atomized sample and the interaction volume, but also provides the possibility to perform microanalysis on solid samples. RIS/RIMS has been used successfully for selective post-ionization of sputtered neutral species, proving powerful ultratrace analysis capabilities below atomic fractions of $10^{-9}$ by removing only a few monolayers of the substrate. One such application is the detection of Al in brain tissue homogenates with a spatial resolution of 100 μm. When RIMS is combined with techniques for pulsed atomization, however, it becomes closely related to many other analytical techniques and thus under these situations has
6.1 Introduction to Diode Lasers and Their Use for Analytical Applications

6.1.1 Historical Development of Diode Lasers

Although the diode laser was invented before the dye laser, for a long period of time it was not able to compete successfully with the dye laser for spectroscopic applications. The reason was the poor performance of the early diode lasers, which made them unattractive in comparison with dye lasers. They needed to be operated at liquid nitrogen temperatures, the spatial profile of their emission was not stable, their spectral emission was spread over many cavity modes, the output intensity was not always linear with injection current, and their lifetimes were not very impressive. The development of diode lasers during the 1970s and 1980s has implied, however, that most of the problems associated with early diode lasers have been overcome. Today, there are handy single-mode room-temperature diode lasers with a number of unique and attractive properties, of which rapid tunability and low noise are two of the most important.

6.1.2 Spectroscopic Applications of Diode Lasers

Diode lasers have found use mainly for fundamental studies – atomic and molecular spectroscopy, environmental monitoring, particularly remote sensing, and analytical applications – but also for a variety of other purposes (e.g. studies of effects of collisions and evaluation of absolute number densities of atoms in atomic reservoirs). Although the general properties of diode lasers have been reviewed repeatedly, the spectroscopic properties of commercial laser diodes firing in the visible and near-infrared regions have been specially addressed by a handful of authors, of which the reviews by Franzke et al. and Fox et al. are of particular interest for spectrochemical analysis. Pioneering work towards bringing diode lasers into the field of spectrochemistry has been done primarily and extensively (but not exclusively) by the groups of Niemax et al. and Winefordner et al.

Despite a number of advantages of diode lasers, a crucial drawback is the lack of lasers that can operate directly at visible or UV wavelengths. The number of elements today that can be studied efficiently by diode laser spectroscopy is therefore somewhat limited. Only a few elements can be detected using diode laser light directly and around 50 can be detected utilizing frequency-doubled diode laser light. The atomic species that have been detected so far by diode laser spectroscopy in various atomizers (primarily flames or furnaces) for analytical purposes are Ba, Br, Ca, Cl, Cr, Cs, Eu, K, Li, Pb, Rb, Sr, and Ti amongst which Li and Rb are the most frequently studied, primarily due to strong transitions from the ground state at wavelengths that can be produced rather easily by diode lasers. Issues that have been addressed are the multi-element capability...
of diode laser spectrometry,\cite{42,464} the isotope selectivity of the technique,\cite{359,461,479,492,509} and the use of diode laser techniques for assessment of the elemental content in samples with complex matrices.\cite{513} Also, the concept of frequency-doubling of diode laser light has received a certain amount of attention lately.\cite{514–516}

A number of molecular species have been detected by diode laser light for remote-sensing applications.\cite{467,468,473,517,518} A somewhat more limited number of molecules have been detected for analytical applications. They have been detected either directly (e.g. water vapor\cite{519,520}) or indirectly (e.g. C₃F₇Cl₂, CCl₄, CHF₃ and O₂) by detection of Cl, F and O in a DC discharge.\cite{496} A good review of the field of analytical molecular spectroscopy with diode lasers has been given by Imasaka.\cite{580}

The detection capabilities for various species differ considerably, depending on the type of atomizer, the transition (i.e. population of the lower laser-connected level and transition probability) and the detection technique used. Diode lasers have been used for spectrochemical purposes with a variety of techniques, e.g. fluorescence techniques,\cite{225,504,516} ionization techniques,\cite{278,352,460–463,476,479,509,521} noise detection techniques\cite{511} and, last but not least, absorption techniques.\cite{477,478,481,494,496–498,505,508,512,522} Although very low detection limits can be obtained by applying diode lasers to the RIS/RIMS technique (which has to be performed under low-pressure conditions in rather complex instrumental set-ups),\cite{11,19,274,278} it has been found that FM or WM techniques significantly improve the detectability of various species using absorption spectrometry under far more versatile conditions.\cite{42,464} The following presentation of the use of diode lasers for analytical spectrometric applications will therefore be devoted to modulated (mostly WM) diode laser absorption techniques.

6.2 Frequency-modulation versus
Wavelength-modulation

The general approach of modulation techniques comprises modulating the frequency (or the wavelength) of the laser light (most conveniently done by modulating the injection current to the laser diode), transmitting the light through the species cloud to be analyzed, and analyzing the detector signal at the modulation frequency (or at some frequency related to this). This process significantly reduces noise from the laser (primarily 1/f noise) by shifting the detection to higher frequencies where the noise is less significant. It also removes baseline offsets, slopes or even some curvature of the background (depending on the mode of operation).

Although being basically the same, the techniques utilizing a modulation of the frequency (or wavelength) are referred to as WM or FM techniques, depending on the relative sizes of the various modulation parameters and the means of detection.\cite{42,466}

WM techniques are characterized by a modulation frequency, fₘ, that is much smaller than the half-width at half-maximum of the absorption peak, Δνₚ (i.e. fₘ ≪ Δνₚ).\cite{42,521} The signal is detected at a suitable harmonic of the modulation frequency (most often at 2fₘ) using a lock-in amplifier. The optimum conditions for WM techniques include, among other things, a modulation amplitude, νₛ, that is a few times larger than the half-width at half-maximum of the absorption profile (νₛ = 2.2Δνₚ for 2f detection, νₛ = 3.9Δνₚ for 4f detection, etc.).\cite{42} This implies, in turn, that the modulation frequency is smaller than the modulation amplitude (i.e. fₘ ≪ νₛ).

When atmospheric pressure-broadened absorption profiles are detected (whose widths often are in the gigahertz range), the modulation amplitude therefore needs to be in the gigahertz range but the modulation frequency (often limited by the performance of the lock-in amplifier) is in the 10–100 kHz range. The use of modulation frequencies in the mid-kilohertz range implies that the influence of laser excess noise has been reduced significantly (although not necessarily fully eliminated).

FM techniques, on the other hand, pioneered by Bjorklund in 1980,\cite{524} and investigated by numerous authors since then,\cite{46,524–532} utilize, under optimum conditions, a modulation frequency that is larger than the width of the absorption peak (i.e. fₘ > Δνₚ). Such a high modulation frequency will impose sidebands (in frequency space) whose spacing is equal to the modulation frequency. By detuning the center frequency of the laser light by an amount equal to the sideband spacing, a sideband will be placed atop the absorption profile. One of the two sidebands will then be absorbed by the analyte. Detection is then achieved by feeding the signal from the detector to a mixer in which this signal is mixed with a reference signal (at frequency fₘ), thus producing the sums and differences of these two signals (often referred to as heterodyning). The resulting signal, which is proportional to the difference in electrical field amplitude of the two sidebands, and therefore also the density of analyte species, can then often be detected directly by ordinary (fast) electronics. In order to optimize the signal strength, preferably only one sideband on each side of the carrier should be produced. This can be achieved if the modulation frequency also is larger than the FM amplitude (i.e. fₘ ≫ νₛ).

This technique has found its best use for the detection of various molecular species under low-pressure conditions (often in multipass cells). Typical modulation frequencies for the FM techniques are in the high megahertz range.
or occasionally around a few gigahertz), which is larger than the typical (often Doppler-broadened) absorption profiles of molecules.\(^{(33)}\) Because excess laser noise is negligible at such detection frequencies, it should, in principle, be possible to obtain shot-noise-limited detection limits with FM techniques.\(^{(528, 529)}\) FM techniques in most cases should therefore outperform WM techniques when it comes to detection power.\(^{(46)}\) However, this has not always been the case in practice. The high modulation frequencies involved put large demands on the instrumentation and increase the complexity of the system considerably. The instrumentation used therefore does not always fulfill all simultaneous requirements for optimum detectability. This is particularly the case when atomic species are to be detected under atmospheric pressure conditions (in which absorption profiles can have widths in the 5–10 GHz range). The rather complex instrumentation is also the prime drawback to the widespread use of FM techniques. Another reason why FM techniques do not outperform WM techniques (despite a lower inherent noise) is the existence of background signals (which, in many practical cases, is the limiting factor for analytical applications). Hence, despite the inherently higher detectability of FM techniques, WM techniques are still often used for the detection of species for spectrochemical purposes\(^{(495–499, 508, 510, 513, 522, 531, 534–539)}\) whereas FM techniques have been used almost exclusively for gas species analysis.\(^{(517, 520, 526–533, 540)}\) We will therefore only discuss the WM technique below. The reader is referred to the literature for a discussion of FM techniques.\(^{(42, 43, 528, 524–533, 540)}\) Thorough investigations and comparisons of (theoretical as well as experimental) various FM and WM techniques have been done by Silver\(^{(42)}\) as well as Bomse et al.\(^{(46)}\)

### 6.3 Wavelength-modulation Spectrometry

#### 6.3.1 Instrumentation

A typical experimental set-up for WM spectrometry is shown in Figure 20. Wavelength-modulated light from a diode laser is directed through an atomizer onto a detector. The detector output is fed to a lock-in amplifier (through a preamplifier when applicable). The output of the lock-in amplifier constitutes the final signal to be registered and stored by a computer.

There are a few different modes of detection for the WM techniques. The most common is 2\(f_m\) detection (i.e. detecting the absorption at twice the modulation frequency, 2\(f_m\)).\(^{(43, 495–499, 508, 510, 513, 522, 531, 534–538, 541–544)}\) although occasionally higher harmonics (4\(f_m\) and 6\(f_m\)) have been used.\(^{(467)}\) Reasons for this are that: the 2\(f\) output is intuitively the harmonic that carries the main part of the analytical signal in WM spectrometry (see discussion below); it produces the largest WM signals; and it eliminates (or reduces significantly) both constant and linearly sloping baselines. Another attractive feature is that the signal peaks at the absorption line center.

6.3.2 Theory

6.3.2.1 Absorption Process and Nomenclature For absorption measurements, the detector signal, \( S_D(v, v_0) \), can be written as shown in Equation (63):

\[
S_D(v, v_0) = \kappa I_0 e^{-\rho L_0(v-v_0)}
\]

(63)

where \( v \) is the frequency of the laser light, \( v_0 \) is the center frequency of the absorption profile, \( \kappa \) is an instrumentation constant (including a photodiode response and an amplification function) that relates the light intensity impinging upon the photodiode to the measured signal, \( I_0 \) is the laser light intensity prior to the interaction region, \( \rho \) is the density of species to be detected (in \( m^{-3} \)), \( L \) is the interaction length, and \( \sigma \) is the absorption cross-section function of the species to be detected at the particular wavelength (frequency) used. Because the absorption cross-section depends on the wavelength of the light (i.e. the frequency), it can be written conveniently as in Equation (64):

\[
\sigma(v - v_0) = \sigma_0 \tilde{\chi}(v - v_0)
\]

(64)

where \( \sigma_0 \) represents the absorption cross-section at the peak of the profile, i.e. \( \sigma(v = v_0) \), and \( \tilde{\chi}(v - v_0) \) is the (peak-normalized) line-shape function for the species to be detected.

6.3.2.2 Wavelength Modulation WM techniques build upon modulation of the laser light wavelength, \( \lambda \), by a sinusoidal modulation frequency, \( f_m \), of the injection current, as shown in Equation (65):

\[
\lambda(t) = \lambda_c + \lambda_a \sin(2\pi f_m t)
\]

(65)

where \( \lambda_c \) and \( \lambda_a \) are the center wavelength and amplitude of the WM, respectively. Because it is more convenient to work with broadening and distribution functions in frequency space, the modulation can be written in terms of frequency (i.e. in Hz), as in Equation (66):

\[
v(t) = v_c + v_a \sin(2\pi f_m t)
\]

(66)

where \( v_c \) and \( v_a \) are the corresponding entities in frequency space, i.e. the center frequency and the modulation amplitude, respectively.

6.3.2.3 The nf Wavelength-modulation Signal This implies that the detector signal has a rather complex time dependence. An intuitive understanding of the origin of the \( 2f \) WM signal in resonance can be obtained from Figure 21. Figure 21(a) displays: the detector signal as a function of frequency for an analyte species with its absorption profile centered around \( v_0 \); the time evolution of the laser light frequency (modulated at a frequency \( f_m \)); and the time-dependent detector signal constructed from both of the former. The absorption profile has been turned through 90° to correlate the frequency axis with that of the laser light modulation. Because the center frequency of the laser light coincides with that of the analyte absorption profile (at \( \lambda_0 \)), the detector signal will experience an absorption maximum twice per modulation period, as shown in Figure 21(a). This explains clearly why the detector output signal will contain a significant amount of \( 2f_m \) frequency components. Figure 21(b) shows the same entities for a linear background absorption. As can be seen, a linear (or constant) background absorption produces no \( 2f_m \) frequency components.

There is, however, no need to study the time dependence of the detector signal directly. A lock-in amplifier is normally used to extract the \( n \)th harmonic of this detector signal, \( \overline{S}_{nf}(v_d, v_a) \), according to Equation (67):

\[
\overline{S}_{nf}(v_d, v_a) = \frac{1}{\pi} \int_{-\pi}^{\pi} S_D[v_c + v_a \sin(2\pi f_m t), v_0] \times \sin(2\pi nf_m t + \phi) \, dt
\]

(67)

where \( \phi \) is a suitable chosen phase and where we, for convenience, have introduced \( v_d \) as the detuning of the modulation center frequency with respect to that of the absorption profile, \( v_d = v_c - v_0 \). This implies in practice that \( \overline{S}_{nf}(v_d, v_a) \) is the \( n \)th Fourier component of the time-dependent detector signal, \( S_D(v_c + v_a \sin(2\pi f_m t), v_0) \).

Arndt\(^{545}\) has shown that the signal strength of the \( n \)th harmonic can be expressed in terms of an integral as shown in Equation (68):

\[
\overline{S}_{nf}(v_d, v_a) = (-1)^n(2 - \delta_{n0}) \int_{-\pi}^{\pi} S_D[v_c - v', v_0] \times \frac{\pi}{T_n}(v'/v_a) \, dv'
\]

(68)

where \( \delta_{n0} \) is the Kronecker delta and \( T_n \) is the Chebyshev polynomial of degree \( n \).

An \( nf \) WM spectrum of the species to be detected, \( \overline{S}_{nf}(v_d) \), can be created by slowly scanning the center frequency across the absorption profile (i.e. the detuning) for a given modulation amplitude.

For the case when the medium is optically thin, the exponential factor in Equation (63) can be approximated with the first two terms in its series expansion; thus, the \( nf \) WM signal, \( \overline{S}_{nf}(v_d, v_a) \), can be written in terms of the \( n \)th harmonic of the line-shape function, \( \tilde{\chi}_n(v_d, v_a) \), according to Equation (69):

\[
\overline{S}_{nf}(v_d, v_a) = -\kappa I_0(\rho L_0 \sigma_0) \tilde{\chi}_n(v_d, v_a)
\]

(69)

The \( nf \) lock-in output signal depends not only on the detuning, the amplitude of the modulation, \( v_a \), and the width of the absorption profile, \( \Delta \nu_\sigma \), but also on the particular form of the absorption profile. The general
Figure 21 Absorptions, modulated laser light frequencies and resulting detector signals for the absorption profile (a) and for linear background absorption (b).
form of a single absorption transition has a Voigt form, originating from a convolution of a Lorentzian-broadened homogeneous profile (resulting from collision broadening) and a Gaussian-broadened inhomogeneous profile (resulting from Doppler broadening).

There are analytical expressions for the \(nf\) WM signal for only two limiting cases: when small modulation amplitudes are being used \((v_\alpha \ll \Delta v_p)\); and when homogeneous broadening dominates the inhomogeneous profile under optically thin conditions (so that the \(nf\) WM signal is directly proportional to the \(nth\) harmonics of a Lorentzian function). Equation (67) or (68) therefore has

\[
\bar{x}(t) = \frac{1}{1 + [\bar{v}_d + v_\alpha \sin(2\pi f_m t)]^2}
\]

which is valid for arbitrary modulation amplitudes and has been derived previously by Arndt,\(^{545}\) as shown in Equation (72):

\[
\bar{x}_n(\bar{v}_d, \bar{v}_a) = \frac{2 - \delta_{n0}}{2} \left\{ \left( (1 - \bar{v}_d) - \bar{v}_a \right)^n - (1 - \bar{v}_d) \right\}^{\frac{n}{2}} \sqrt{(-1)^n + c.c.} \]

where \(i\) is the imaginary unit and \(c.c.\) represents the complex conjugate.

Although the above expression is exact, it is not always suitable for direct use because it is cast in terms of complex numbers. Klucznisky and Axner showed recently that this expression can be written more conveniently as shown in Equation (73):

\[
\bar{x}_n(\bar{v}_d, \bar{v}_a) = \frac{A_n}{(\bar{v}_a)^\eta} B_n + C_n S_3 + D_n S_4 \sqrt{2R}
\]

where \(S_3 = \sqrt{R + M}, S_4 = \sqrt{R - M}, R = \sqrt{M^2 + 4(\bar{v}_d)^2}, M = 1 + (\bar{v}_d)^2 - (\bar{v}_a)^2,\) and the four parameters \(A_n - D_n\) take different values (in terms of \(\bar{v}_a\) and \(\bar{v}_d\)) depending on the order of the harmonics.\(^{533}\) The components for the first five harmonics are given in Table 6.

Typical 1f, 2f, 4f, and 6f WM spectra from a single-peak (Lorentzian-broadened) transition are exemplified in Figure 22. Each spectrum is evaluated for the modulation amplitude that maximizes that particular \(nf\) WM component (2.0, 2.2, 3.9 and 7.4, respectively; see section 6.3.3 below). As can be seen from the graph, the even harmonics have their maximum value at the position of the peak of the absorption profile, whereas the odd harmonics have it elsewhere, and the 2f signal gives rise to the largest signal of all even components.

**Table 6** The \(A_n - D_n\) coefficients for the five lowest harmonics (i.e. \(n = 0 - 4\)) of the Fourier components of a Lorentzian absorption profile (Equation 73)

6.3.3 Maximum Signal Conditions

The conditions for maximization of the WM signal have been scrutinized by a number of authors. Cassidy and Reid calculated relative peak heights for the 2nd, 4th, 6th and 8th harmonics of a pure Lorentzian profile. Wilson used numerical integration to obtain the three first harmonics of both Gaussian and Lorentzian profiles. Silver determined the optimum values of the modulation index \( m \) for both Gaussian and Lorentzian profiles for the 1st, 2nd, 4th and 6th harmonics. He found the optimum modulation indices to be: 1.6 and 2.0; 2.1 and 2.2; 3.6 and 3.9; and 5.2 and 7.4, respectively. Rojas et al. and Gustafsson et al. investigated three different issues of the 2f WM technique: when atoms are detected under not necessarily optically thin conditions; for atoms with complicated (multi-line) atomic structure (a special study was performed of the 780-nm transition in Rb, which constitutes two isotopes each with six individual close-lying transitions); and the extent to which a low-pressure cell can be used as a wavelength reference for 2f WM experiments made under conditions of atmospheric pressure and high temperature (i.e. a GF). The same authors also investigated the temperature dependence of the 2f WM technique.

6.3.4 Signal-to-noise Ratios

The most extensive analysis of the S/N conditions for diode-laser-based modulation techniques has been given by Silver and Bomse et al. They discussed the concept of S/N for both WM and FM techniques and their conclusions are based upon experiments made with a liquid-nitrogen-cooled infrared lead–salt diode laser, working in the 8-µm wavelength range, used for detection of NO in a multipass cell. Although the conditions are not typical of those when diode-laser-based modulation techniques are used for analytical atomic spectrometry, some of their conclusions are of importance.

They defined an intrinsic S/N (power) ratio as the ratio of the square of the time-averaged analytical signal and the sum of the squares of the noise contribution from internal sources of noise, i.e. laser-induced detector
shot-noise, detector–preamplifier thermal noise, residual amplitude modulation (RAM)-induced noise, and laser excess noise. They analyzed their results, however, in terms of extrinsic sources of noise, in this case that originating from etalon background signals (see section 6.3.5).

In the absence of noise from RAM and background signals, the authors concluded that under their experimental conditions (a laser with 11 µW of output power) the WM signals ought to be dominated by laser excess noise at low modulation frequencies and by detector noise at higher frequencies. Shot-noise-dominated situations should, under optimum conditions (i.e. in the absence of RAM and background signals), be obtained for a combination of higher laser powers (in their case above 40 or 560 µW, depending on the detector used) and high modulation frequencies (in the megahertz range). At low or medium modulation frequencies the detectability of WM techniques should therefore (again under optimum conditions) be limited by laser excess noise (which is the dominating noise in the kilohertz range). \(^{42}\)

6.3.5 Background Signals

In reality, there are background signals that can compete with the analytical signal when small enough quantities/concentrations of analyte are to be detected.

RAM (originating from an associated modulation of the intensity with the laser diode injection current) is a type of background signal frequently referred to. Although predicted by the theory presented by Silver, \(^{42}\) and used by a number of authors since then for describing their background signals, it was first shown by Zhu and Cassidy \(^{523}\) and then discussed further by Kluczynski and Axner \(^{523}\) that there is no \(nf\) RAM signal for \(n \geq 2\) (including \(2f\) RAM) as long as the modulation of the intensity is linear with that of the injection current. The incorrect prediction of a \(2f\) RAM signal from a linear intensity modulation originates from an uncritical application of a theoretical formalism developed for FM spectrometry (in which the intensity modulation is described as a modulation of the electrical field strength of the laser light instead of the intensity) to the WM technique.

The dominating cause of background signals is instead multiple reflections between various optical surfaces (which thus act as etalons). Because the transmission through an etalon is strongly wavelength dependent, the detector will experience a wavelength-dependent modulation of the intensity that will contain the same higher harmonics as the analytical signal. \(^{523}\) The drift and fluctuations of these background signals are often the limiting factors to the WM technique. Therefore, unless any special concerns are taken, the detection power of modulation techniques is often limited by the noise and drift in the background signal originating from multiple reflections in the system rather than any of the intrinsic sources of noise, giving rise to detection limits (fractional absorbencies) in the \(10^{-5}\) range. \(^{43,46,467,495,498,513,517,530,544,548}\)

6.3.6 Means to Reach Optimum Conditions

Remedies for reducing etalon effects comprise: eliminating the use of optical surfaces that are perpendicular to the direction of the laser beam; antireflection coating; replacing parallel plates with wedges; and modulating either the position of the surfaces \(^{499,520,549-551}\) or the atomization at a frequency different from that modulating the laser wavelength \(^{498,550}\).

6.3.6.1 Dithering of Optical Surfaces

Bomse et al. \(^{46}\) concluded that with piezocrystal dithering of appropriate optical components the optimum conditions for \(1f\) and \(2f\) WM spectrometry comprise modulation of the frequency at a rate between 100 kHz (which were sufficient for bringing the \(1f\) noise down to levels below that of the background signals in their experiment) and 20 MHz (at which instrumentation difficulties arose). They also concluded that neither of the FM techniques investigated could outperform the high-frequency WM techniques (although their theoretical treatment predicted that the one-tone FM technique should provide an almost fivefold improvement over high-frequency WM spectrometry). They attributed this to instrumental deficiencies (low detector sensitivity and inefficient radiofrequency coupling of the modulation current to the laser). The authors concluded finally that, owing to the high sensitivity of the etalon background signals to small changes in optical alignment, the reproducibility of the final detection power of the WM techniques (< \(10^{-6}\) ) depended strongly on the details and stability of the optical alignment and variations in the effectiveness of the etalon reduction scheme.

It is important to point out, however, that dithering the position of various surfaces has the drawback that it can only eliminate background signals from etalons created between two different optical components. Any possible etalon created inside a component (i.e. between the front and back surface of the same optical component) cannot be eliminated by that technique. \(^{523}\) Such etalons can therefore set the ultimate level for the background signal in conventional WM spectrometry and thereby also the S/N level. \(^{523}\)

6.3.6.2 Modulation of the Atomization

An efficient way around these residual problems is to modulate also the atomization process and detect the signal at a combination of the ordinary \(nf\) frequency and that of the atomization. Although modulation of an optical surface is rather straightforward to achieve, modulation
of the atomization process is more difficult in thermal atomizers such as flames and furnaces, although it can be used with advantage using various types of plasmas. The most impressive demonstration of a double-modulation technique that has been performed so far is the detection of Cl atoms in a modulated low-pressure microwave-induced plasma by Liger et al.\(^{499}\) The authors showed that spurious etalon effects, background absorption, residual diode-laser-amplitude modulation and the noise that accompanies these entities could be suppressed by the use of a double-modulation technique in which both the diode laser wavelength and the plasma were modulated (although at different frequencies). This double-modulation technique enabled a detection limit of \(1 \times 10^{-6}\) AU to be obtained for Cl atoms in a modulated low-pressure microwave-induced plasma (with a time constant of 1 s).

6.3.6.3 Double-modulation, Dual-beam, and Logarithmic Detection In order to eliminate laser excess noise and signal variations due to changes/drifts of the optical transmittance, a double-beam arrangement with logarithmic subtraction of sample and reference detector currents was developed by the same set of authors.\(^{499}\) As is exemplified in Figure 23, the logarithmic amplification not only makes the system independent of variations in the radiation intensity but it also enables suppression of the noise by decoupling the modulations of the intensity and wavelength. A detection limit of \(2 \times 10^{-7}\) AU limited by shot-noise could finally be established. The authors conclude finally that preliminary experiments showed that shot-noise was the dominating source of noise up to time constants of about 1000 s in their experiments and that as a consequence it should be possible to reach detection limits as low as \(6 \times 10^{-9}\) AU. If such detection powers can be realized, WM techniques would surely find a much broader applicability in spectrochemical analysis than they have today.

6.4 Conclusions and Outlook

Frequency- and wavelength-modulation diode laser absorption spectrometry (FM/WMDLAS) has the great potential to outperform conventional AAS in the future. There is no doubt that the technique has better sensitivity, LDR and selectivity than the AAS technique. The most significant drawback of FM/WMDLAS today is the lack of diode lasers producing light in the visible and UV regions.

7 CONCLUSIONS

It is clear that laser light, with its narrow bandwidth and high spectral irradiance, is ideal for selective interactions with atomic and molecular species. Extraordinary results have been achieved in a number of application areas,\(^{47–52}\) of which the cooling and trapping of single atoms or ions and the creation of Bose–Einstein condensates\(^{552}\) in the fields of atomic and molecular spectroscopy and quantum optics are just a few impressive examples. Despite many impressive demonstrations in the field of analytical spectrometry,\(^{21,48}\) laser-based spectroscopic techniques so far have been techniques only for the physical or chemical laboratories around the world. The reasons for this are that: the production of laser light has not been as carefree as first anticipated; the cost of tunable laser systems has been too high; and laser-based techniques are basically single-element detection techniques.

With the advent of single-mode, tunable diode lasers (and maybe also new OPO-based systems), however, and the new application areas that these handy types of lasers now start to pervade, the prospects for a more regular use of laser-based spectroscopic techniques
for analytical spectrometry seems to be better than ever before. If such techniques can be developed and commercialized in a proper manner in the future, then the regular analytical laboratory will be able to benefit from the extraordinary properties of laser-based spectroscopic techniques regarding sensitivity and selectivity (including various types of powerful means of background correction).

Even if laser-based spectroscopic techniques do not find their way onto the commercial market as regular techniques for trace species determinations, they will always have their role in certain types of applications. The nonintrusiveness of the techniques, for example, makes them attractive in certain situations, e.g., when samples with long-lived but toxic radioactive species are to be analyzed. In addition, as has been demonstrated repeatedly, their capabilities as diagnostic tools are indeed unmatched. Their applicability for remote-sensing applications is also unparalleled.

Looking back to what the joint community of laser spectroscopists has achieved during the last 20 years, it is difficult not to be impressed. Even in such a perspective, it is more difficult than ever to try to prophesy what the future will bring in this area: where will this field of science stand 20 years from now? Can we then, maybe, really count the atoms in an unknown sample?

ACKNOWLEDGMENTS

The author is indebted to all his colleagues in the Laser Physics Group at the Department of Experimental Physics at Umeå University for their continuous support during the writing of this review article. The author would also like to thank the Swedish Natural Science Research Council, the Swedish Research Council for Engineering Sciences (under project nos 251-97-733 and 288-98-40) and the Faculty of Science and Technology at Umeå University for various types of economic support, without which this review would never have become a reality.

Laser-induced breakdown spectroscopy (LIBS) is a novel method of elemental analysis based on a laser-generated plasma. Pulses from a laser are focused on a sample to atomize a small amount of material resulting in the formation of a microplasma. Because of the high plasma temperature, the resulting atoms are electronically excited to emit light. The plasma light is spectrally resolved and detected to determine the elemental composition of the sample based on the unique emission spectrum of each element. Because of the simplicity of the method, it is suited for analyses that cannot be carried out using conventional methods of atomic emission spectroscopy (AES). This is particularly true for measurements that must be conducted outside of an analytical laboratory. A particular advantage of LIBS is the ability to analyze most types of samples without any preparation. This means that samples can be interrogated in situ, providing rapid measurement capability and permitting the method to be used in the analysis of gases, liquids, and solids in a variety of different sampling configurations. Although LIBS provides sensitive detection for many elements, it is not an ultrasensitive detection technique. In addition, under field conditions, the method typically does not provide the high accuracy and precision offered by laboratory-based methods of AES.

1 INTRODUCTION

LIBS is a method of elemental analysis based on AES. Three basic steps are involved in AES measurements. These are (1) vaporization of the sample to produce free atoms, (2) electronic excitation of the atoms to induce optical emissions at discrete wavelengths indicative of the atoms, and (3) collection, recording and analysis of the optical emissions. Atoms in the sample are identified by their unique spectral emissions or ‘fingerprint’ spectra. In conventional AES methods, a plasma source is used for steps (1) and (2). Conventional plasma sources include arcs and sparks and the inductively coupled plasma (ICP). These sources all require the use of some physical device to deliver electrical energy to form and sustain the plasma such as metal electrodes (for sparks and arcs) and a metal coil (ICP). In LIBS, however, the plasma or laser spark is formed by intense optical radiation focused on the sample to produce dielectric breakdown leading to plasma formation.

The basic steps involved in a LIBS measurement are shown in Figure 1. Focusing a laser pulse on the sample produces local heating of material in the focal volume resulting in the ejection of a small mass of material in the form of solid particles, liquid drops, and atomic vapor. Via interactions between the incident laser pulse, electrons, and free atoms, a hot plasma is formed above the target surface. Through collisions between the different species in the plasma the atoms are electronically excited to emit light at discrete frequencies unique to each species. These unique spectral ‘fingerprints’ permit identification of the species through collection and analysis of the plasma light. Because the laser plasma is formed by a laser pulse of short duration (typically 5–20 ns), the plasma decays and...
accompanied by a bright flash of light and a loud ‘snap’ onto the surface of a solid target. Plasma formation is pulse directed either into a material (gas or liquid) or highly ionized gas, within the focus of the laser. The LIBS method is based on the formation of a plasma, which is strongly dependent on the parameters of the laser pulse, such as the physical characteristics of the target sample, and the characteristics (e.g. temperature, electron density) are formed on the sample surface. Because the LIBS plasma is formed by light, it represents a unique method of elemental analysis having many advantages over conventional methods of AES. These advantages include (1) situ analysis (only optical access to the sample is required), (2) little or no sample preparation, and (3) the ability to sample gases, liquids, and solids directly. On the other hand, like other plasma-based methods of AES, it provides for (1) simultaneous multi-element detection and (2) exhibits good sensitivity for many elements. The main limitations of LIBS relate to the sampling characteristics of the technique. Specifically, that the amount of sample vaporized and the plasma characteristics are strongly dependent on the parameters of the laser pulse, the physical characteristics of the target sample, and the sampling geometry. These limitations are manifested in terms of limited accuracy and precision compared to more conventional analytical methods.

2 THEORY

2.1 Fundamentals of Laser-induced Breakdown

The LIBS method is based on the formation of a plasma, or highly ionized gas, within the focus of the laser pulse directed either into a material (gas or liquid) or onto the surface of a solid target. Plasma formation is accompanied by a bright flash of light and a loud ‘snap’ emanating from the focal region. Detailed analysis of the physics of laser-induced breakdown can be found elsewhere. Briefly, the plasma is formed by the transfer of optical energy from the laser pulse to atoms, ions, and electrons resulting from deposition of energy into the target. This energy transfer occurs through the process of inverse bremsstrahlung absorption involving interactions between free electrons and atoms and ions. In order for the inverse bremsstrahlung process to be of sufficient strength to produce breakdown, a high density of electrons (and ions) must be present. Two mechanisms accounting for electron (e\(^{-}\)) production are described by two processes involving atoms (M) (Equations 1 and 2):

\[
\begin{align*}
\text{e}^{-} + \text{M} & \rightarrow 2\text{e}^{-} + \text{M}^{+} \\
\text{M} + n\text{hv} & \rightarrow \text{M}^{+} + \text{e}^{-}
\end{align*}
\]

Mechanism (1) involves absorption of laser radiation by an electron during a collision with a neutral atom. If sufficient energy is absorbed to ionize the atom then two free electrons result. If this process continues generating two electrons for each one electron involved in the collision then what is termed cascade electron growth results. Mechanism (2) is termed multiphoton ionization. In this process a number of photons (n) each of energy \(\text{hv}\) are absorbed simultaneously by an atom resulting in a free electron and an ionized species. In order for this process to occur, it must be that \(n\text{hv} > \text{Ip}\), where \(\text{Ip}\) is the ionization potential of the atom.

2.2 Post-breakdown Phenomena

Following formation of the initial plasma by the laser pulse, the plasma passes through several different phases. Detailed descriptions of these can be found in the literature. Here a brief overview is presented. Once free electrons have been generated in the focal volume, the plasma grows through the process of inverse bremsstrahlung (IB) of which two types can be identified, electron–neutral and electron–ion, each being important during different stages of plasma growth. When few electrons are present, electron–neutral IB (IB\(_{e-n}\)) predominates but as plasma formation continues to the point at which about 1% ionization occurs, electron–ion IB (IB\(_{e-i}\)) becomes the chief absorption process. The absorption coefficients (\(\alpha\)) for each type are given in Equations (3) and (4):

\[
\begin{align*}
\alpha(\text{IB}_{e-n}) & = 1 - \exp \left( -\frac{\hbar c}{\lambda kT} \sum Q_i n_i n_j \right) \\
\alpha(\text{IB}_{e-i}) & = 1 - \exp \left( -\frac{\hbar c}{\lambda kT} \left( \frac{4\pi^2\lambda^3}{3\hbar c^4 m_e} \right) \times \left( \frac{2\pi}{3m_e kT} \right)^{1/2} \sum \frac{z_i^2 n_i g_i}{n_e} \right)
\end{align*}
\]
where:

\[ Q_j = \text{average cross-section for absorption of a photon (wavelength } \lambda) \text{ as a result of collisions with the } j \text{th species} \]
\[ n_e = \text{electron number density} \]
\[ n_i \text{ and } n_j = \text{number density of } i \text{th and } j \text{th species} \]
\[ z_i = \text{charge of the } i \text{th species} \]
\[ g_i = \text{Gaunt factor}. \]

The temperature regime over which the change from the two types of IB absorption occurs is between 6000 and 10,000 K, which is also the temperature regime of a LIBS plasma. Both absorption coefficients decrease with increased temperature with the coefficient \( \alpha(\text{IB}_e-i) \) having the stronger dependence. Because this coefficient depends on the square of the electron density compared to the linear dependence for \( \alpha(\text{IB}_e-n) \), electron–ion IB predominates as the temperature and hence the electron density increase.

Following the formation of an absorbing plasma within the focal zone, the plasma will continue to grow away from the surface towards the direction of the incoming laser pulse. This growth occurs because the laser pulse feeds energy into the plasma with most of the absorption occurring in the upper boundary region of the plasma as shown in Figure 1. This process accounts for the inverted cone shape of the plasma observed in the focal volume. The exact character of the evolving plasma will depend on parameters of the laser pulse (irradiance, spot size, wavelength) and the surrounding atmosphere. Three distinct evolutionary paths can be described in terms of the characteristics of absorption and shock or pressure waves emanating from the focal zone. The three types are classed as either laser-supported combustion (LSC), laser-supported detonation (LSD) or laser-supported radiation (LSR) waves. The interested reader is directed to the literature for a discussion of the characteristics of each type.\(^{(4,6)}\)

### 2.3 Dynamics of Laser Ablation

The interaction between a laser pulse of high power density and a material is a complicated process. A thorough consideration of the interaction depends on characteristics of the laser pulse and the material. Several authors have considered the interaction in detail.\(^{(7,8)}\) Here we present a brief description of the main processes involved.

The laser pulse incident on the surface interacts mainly with the electrons in the bulk material. These interactions involve absorption of energy from the pulse by electrons that in turn collide with other electrons and with other constituents of the matrix. These collisions result in the transfer of energy from the laser pulse to the material in the focal volume resulting in heating. This heating occurs rapidly and results in melting of a thin surface layer with some of the heat being conducted away into the bulk matrix. Because of the high power densities on the surface however, the melted material continues to be heated and when the deposited energy exceeds the latent heat of vaporization, atomized material is ejected from the surface. Some solid and liquid particles may also be ejected via the strong shock/pressure waves generated at the surface.

An estimate of the minimum laser pulse-power density required to produce vaporization \( (P_{\text{min}}) \) can be obtained from Equation (5):

\[ P_{\text{min}} = \rho L_v \kappa^{1/2} \Delta t^{-1/2} \]

where:

\[ \rho = \text{mass density of target} \]
\[ L_v = \text{latent heat of vaporization} \]
\[ \kappa = \text{thermal diffusivity of target} \]
\[ \Delta t = \text{pulse length}. \]

For pure aluminum metal, \( P_{\text{min}} \approx 1.75 \times 10^8 \text{ W cm}^{-2} \).

Note that this calculation assumes all incident pulse energy goes toward heating therefore representing a lower bound on the minimum power density required for vaporization.

Although ejection of material can proceed over a wide range of power densities, two distinct operating regimes can be identified, one most favorable for quantitative analysis. For low power densities \( (<10^8 \text{ W cm}^{-2}) \), the ejection of positive ions of volatile elements such as Na and K is readily observed from the surface whereas more refractory elements (Mo, W, etc.) remain in the bulk material. In this case the ejected material will not be representative of the bulk composition and therefore operation at these low power densities is not appropriate for quantitative analysis.

At higher power densities \( (>10^9 \text{ W cm}^{-2}) \) significantly more laser energy is transferred into the material resulting in a greater degree of vaporization and atomization of a more representative distribution of elements from the molten pool. In addition, because of the greater mass of ablated material, the incident laser pulse also interacts with electrons and ions in the plume above the surface resulting in increased excitation of atomized species. Because laser ablation is more pronounced at higher power densities, a visible depression or crater is left on the target surface in the interaction zone. Typically, the mass of material ejected from the surface is very small. Assuming again that all energy goes toward the ablation process, a simple calculation shows that the upper limit to the amount of material that can be vaporized by a 100 mJ pulse is about 6.6 \( \mu \text{g} \). Because of reflection losses...
at the surface and the conversion of some of the incident energy into light and sound, the amount of material actually vaporized will be significantly less. Measurements indicate, for example, that about 10 ng are ablated from aluminum metal using a laser pulse of 175 mJ.

3 LASER-INDUCED BREAKDOWN SPECTROSCOPY INSTRUMENTATION

3.1 General
A diagram of a generalized LIBS instrument is shown in Figure 2. The main components include a laser, a method of spectrally resolving or of spectrally selecting a certain narrow region of the spectrum to monitor, and a method of detecting the spectrally selected light. The specifications of each component as well as the method of sampling used will depend on the application. Factors to consider include (1) the elements to be monitored (number and type), (2) the characteristics of the sample (complexity, homogeneity, etc.), (3) the type of analysis (e.g. a qualitative versus quantitative measurement), and (4) the state of the sample (e.g. gas, liquid, or solid).

3.2 Laser Systems
The parameters important in the specification of the laser to be used for LIBS include (1) pulse energy, (2) pulse repetition rate, (3) beam mode quality, (4) size/weight, and (5) cooling and electrical power requirements. The wavelength of the laser beam is not an important factor in most cases.

Solid state lasers, in particular pulsed and Q-switched Nd:YAG lasers having pulsewidths less than 15 ns, are typically used for LIBS measurements because these lasers are a compact and convenient source of the powerful pulses needed to generate the laser plasmas. The fundamental wavelength of the Nd:YAG laser (1064 nm) can easily be converted to shorter wavelengths (532, 355, and 266 nm) via passive harmonic generation techniques which may have certain advantages in terms of increased energy coupling into a particular sample, but typically the 1064 nm wavelength is used because this provides the highest power density. Other types of lasers, most notably the pulsed CO₂ laser (10600 nm wavelength) and the excimer laser (typical wavelengths of 193, 248, 308 nm) have been used for LIBS. In comparison to solid state lasers, however, these lasers require more maintenance (e.g. change in gases) and special optical materials because their wavelengths lie in the far-infrared and ultraviolet spectral regions, respectively. For this reason these lasers are not widely used.

Another advantage of the Nd:YAG laser is the variety of different sizes available commercially. These range from laboratory-based models which can output a Joule or more of pulse energy at repetition rates between 10 and 50 Hz to small hand-held versions with a repetition rate of 1 Hz and a pulse energy of about 17 mJ. The laboratory models require 208 VAC electrical services of at least 20 A and may require external water cooling or at least a heat exchanger. The hand-held versions are air cooled, and can be operated from batteries or low voltage direct current sources.

3.3 Methods of Spectral Resolution
The basis of a LIBS measurement is the collection and analysis of an emission spectrum. The emission lines of the elements are tabulated in various sources. Examples of emission spectra from three different samples are shown in Figure 3.

All samples contained the element Si having a strong emission at 288.1 nm but each sample differed in the number of other elements present as major and minor species. In general, the greater the number of elements the more complicated the spectrum. The simplest spectrum is that of Si in water [Figure 3a]. Here the Si line appears alone without interferences from either H or O which have few emission lines making the emission spectrum particularly simple. Silicon in aluminum metal is readily observed in Figure 3(b) although lines due to Mg, Al, and Fe are also present. Steel represents a complex matrix because of the large number of Fe lines and steels typically contain a large number of other elements. The Si line from a steel sample is apparent in Figure 3(c) but because it is adjacent to an Fe line it is not completely resolved in this spectrum. Using a spectral resolution method having greater resolving power, however, the Si can be separated to some extent from the adjacent Fe line as shown in Figure 3(d).

The spectra shown in Figure 3 demonstrate that the complexity of the sample will determine the method of spectral resolution needed to monitor the...
Figure 3 Emission line of Si (288.1 nm) observed from different matrices using LIBS. Spectra (a), (b), and (c) were obtained using a spectograph of moderate resolution. (a) Si in water. (b) Si in aluminum alloy. (c) Si in steel. (d) Si in steel obtained using 3x greater spectra resolution than shown in (c).

Figure 4 Methods of spectral resolution of the plasma light using (a) filter-based methods and (b) spectrometer-based methods. T = target; CL = converging lens; F = filter; photomultiplier tube (PMT); SP = signal processing; RFG = radio-frequency generator; AOTF = acousto-optic tunable filter; M = mirror; G = grating; ES = entrance slit; XS = exit slit; AD = array detector; C = computer.

Type of AD or a series of single wavelength detectors positioned behind individual slits.

Diagrams of methods (1) and (2) are shown in Figure 4(a). In the case of the narrow bandpass filter or AOTF, only a single narrow wavelength band is passed through the wavelength selective element. The
transmitted light is then detected using some sort of light detector (section 3.4). The advantage of the fixed wavelength filter is very small size and low weight and cost. The AOTF, on the other hand, is somewhat larger and requires a power supply, but it can be tuned to monitor different wavelength regions. The use of a monochromator or spectrograph is diagrammed in Figure 4(b). The monochromator can be considered a spectrograph with a slit at the exit focal plane so that only a single narrow wavelength region is monitored at one time. The spectrograph, on the other hand, provides simultaneous detection over a wide spectral range because the single exit slit is removed and an AD is used to record the spectrum or a series of exit slits each with its own detector is placed along the focal plane.

The most suitable method of spectral resolution depends mainly on the analysis requirements. Factors that must be considered include (1) the complexity of the sample (i.e. how many elements are in the sample and do these elements have many emission lines or only a few strong lines?), (2) the number of elements to be monitored, (3) whether the elements are to be monitored simultaneously or is sequential detection adequate, and (4) the location of the emission lines in the spectrum.

Although not all possible combinations of the spectral resolution methods can be considered here because of the wide range of factors that will influence the final choice, Table 1 summarizes the capabilities of each method. It should be noted that in the case of the fixed wavelength methods a second, third, etc. fixed wavelength system may be added to provide simultaneous multiple wavelength detection capabilities.

If only a single element or a few elements are to be monitored then narrow bandpass fixed wavelength filters may be the method of choice in terms of simplicity and small size. These filters can be manufactured having a narrow bandpass (down to 0.1 nm) to selectively monitor an element line in complex spectra as shown in Figures 3(c) and 3(d). If, on the other hand, multiple wavelengths are to be monitored using a spectrograph, then the spectral resolution and spectral coverage provided by the instrument must be considered. As spectral resolution increases, spectral coverage decreases. For example, in Figure 3(c) a fairly wide spectral range is shown. However, if Si is the element of interest, there appears to be an interference with an adjacent line. Using a spectrograph having resolution three times greater, results in the spectrum shown in Figure 3(d) with the degree of overlap between the Si line and the adjacent line reduced. There is, however, a loss in the spectral coverage so that element lines at both extremes of the spectrum shown in Figure 3(c) will not be recorded with the instrument of higher resolution. In the case of the monochromator and spectrograph, the spectral resolution or ability to resolve adjacent emission lines is determined by the focal length of the device and the number of lines per millimeter on the grating.

### 3.4 Detectors

The method of spectral selection determines the type of detector used for LIBS measurements.\(^{14,15}\) The simplest detector consists of a photosensitive material that generates a signal proportional to the amount of light incident on the device. These PDs include PMTs and photodiodes. These devices are used with spectral selection methods such as fixed filters, AOTFs, and monochromators. By placing small photosensitive elements (pixels) in either a linear or 2-dimensional array, an AD is produced that provides spatial information concerning the light pattern incident on the array. Common examples of these ADs include photodiode arrays (PDA), charge coupled devices (CCD) and charge injection devices (CID). ADs are used with spectrographs to record the continuous spectrum presented at the focal plane of the instrument. The spectra shown in Figure 3 were obtained using a CCD detector. Each firing of the laser produced a spectrum.

The type of detector determines the method of signal processing. The signal from the PMT, for example, consists of a current that is converted to a voltage by the recording device. The response of a PMT is typically very fast, less than a few nanoseconds, so it can be used to record the temporal variation of the plasma light at the selected wavelength. If multiple wavelengths must be monitored simultaneously, several slit/PMT assemblies

can be placed in the focal plane of a spectrograph with the slit positions aligned to the emission peaks of the elements of interest. Time-resolved detection of an element signal is obtained by electronic processing of the PMT signal using a sample-and-hold circuit.

The spectral coverage provided by an AD is determined by the physical size of the array and the characteristics of the spectrograph. The PDA is a one-dimensional arrangement of diodes that provides spatial intensity information in one dimension. Typical spacing between individual photodiodes is 25 microns so an array of 1024 pixels has a physical length of about 25 mm. The CCD and CID, on the other hand, are two-dimensional arrays of photodiodes that can provide intensity information along two axes. Typical pixel sizes range from $9 \times 9$ microns up to $24 \times 24$ microns and array formats range from $576 \times 384$ pixels up to $3072 \times 2048$ pixels with a large number of other formats in between these extremes.

A generalized method of processing the plasma light using a detector is shown in Figure 5. The short duration laser pulse generates the plasma that typically lives for many microseconds after formation. Using either a PD or AD, the plasma light can be integrated over the entire emission period of the plasma. The resultant signal is shown in Figure 5.

In the case of a PMT, the detector current is stored on a capacitor that charges up to a certain voltage as light strikes the detector. In the case of an AD, the charge is stored on the pixel and then is read out at a later time. The magnitude of the voltage or stored charge is proportional to the number of photons incident on each detector. At the end of the period of light collection, the voltage or charge is read out and the signal levels are reset to zero for the next pulse. Instead of integrating the plasma light over the entire plasma lifetime, it may be useful to only monitor a certain period of light emission as the plasma decays. An example would be to discriminate against the intense white light that emanates from the plasma during the first $1-2 \mu$s. Generally, a gate pulse is applied to the detection electronics that determines the time after plasma formation at which recording of the plasma light is to begin ($T_d$) and the length of time over which the light is collected ($T_b$). In the case of a PMT, the signal is processed by a simple circuit such as a gated integrator that only stores the current from the PMT according to the timing designated by an applied gate pulse. When the gate pulse is high, the current is stored. In the case of an AD, the gate pulse is directed to a microchannel plate image intensifier that only transmits light through to the photosensitive area of the PDA, CCD, or CID when the gate pulse is present.

### 3.5 Examples of Instruments

#### 3.5.1 Laser Microprobe

The first instrument developed for the commercial market based on the laser spark was the laser microprobe. This device combined laser ablation of a solid sample with the spark produced by conventional metal electrodes (Figure 6). In this laboratory-based instrument, the ablating laser pulse produced an aerosol of material above the sample surface that was then interrogated by the spark.
produced by the electrodes. These types of instruments were made by several manufacturers and were on the market for several years. Detailed reviews of applications of these instruments can be found in the literature. Some additional information on the capabilities of the technique can be found in section 6.2.

3.5.2 Field-portable Instrument

Because of recent developments in miniaturization of components used for LIBS, it has been possible to fabricate truly portable LIBS-based instruments. An example is shown in Figure 7. This device consists of a main analysis unit connected to a hand-held probe. The probe contains the laser, focusing optics, and a fiber optic cable to collect the plasma light. The light is transported back to the analysis unit that houses the small spectrograph, detector, and laser power supply. The instrument is operated through the use of a micro or laptop computer. An analysis is carried out by placing the probe on the sample and then firing the laser. The laser can be repetitively fired to average the spectra from many shots and increase measurement accuracy and precision.

The resulting spectrum is then analyzed via software to determine the element signals. Quantitative analysis is possible through calibration of the instrument using calibration standards of known composition.

4 CHARACTERISTICS OF THE LASER PLASMA

The characteristics of the LIBS plasma (e.g. temperature, electron density, size) depend on the state of the sample (gas, liquid, solid) and other parameters such as the pressure and composition of the surrounding atmosphere. Here we present a brief overview of the properties of the laser plasma for different samples.

4.1 On Solids

Solid samples were among the first to be quantitatively analyzed with LIBS. Because most solid targets are opaque at the laser wavelength, the laser plasma is formed on the surface of the solid even though the distance between the target and the focusing lens may be different from the focal length of the lens. As long as the power density is above a threshold value, a laser plasma will be formed. This situation is different from that which occurs in the analysis of a transparent gas or liquid. In these cases, the laser plasma is always formed in the focal volume, the position of which is determined by the focal length of the lens. Because there are a range of lens-to-sample distances (LTSD) over which the plasma can be formed on a solid, the plasma parameters such as temperature and electron density and the amount of material ablated by the pulse have a range of values determined by the LTSD.

For a Nd:YAG laser pulse (186 mJ), typical plasma temperatures range from 6000 to 9500 K with electron densities in the range of $10^{17}$ to $10^{19}$ cm$^{-3}$ immediately after plasma formation. The mass of material ablated from aluminum metal ranges from 5 to 80 ng pulse$^{-1}$. These parameters vary within the specified limits and depend on factors such as ambient pressure and LTSD. As the plasma cools, the temperature and electron density both decrease. Using the white light from the plasma as an indicator, the temporal duration of the plasma ranges out to about 10–20 µs if formed on a metal in air at atmospheric pressure.

4.2 In Gases

The laser spark phenomenon was first discovered by the breakdown of gases shortly after the discovery of the laser. However, it was not until time-resolution was applied that quantitative measurements could be carried out. The LIBS technique allows for the analysis of gases and
combustion products as well as the analysis of aerosols and suspended particles in a gas. The typical precision for the analysis of gases is around 5–8% RSD (relative standard deviation). This value is considerably elevated in the analysis of aerosols and airborne particles to around 30% and is probably due to shot-to-shot differences in sampling particles of different sizes and having different locations in the plasma volume.

The spark formed in a gas has a much higher temperature than that formed on a solid. Although the temperature is dependent upon the ambient gas, values up to 20,000 K have been measured as the initial temperature of the plasma. The plasma cools with time to values as low as 12,000 K at 10 µs after plasma formation. The electron density of this high temperature plasma is about the same as measured for solid samples.

### 4.3 In Liquids

The spark produced in a bulk liquid is significantly different from that produced in a gas or on a solid. The plasma is visibly much smaller and the temporal decay of light emission occurs more rapidly such that useful spectral emissions are absent for times >2 µs. In addition, there is significant temporal overlap between emissions from neutral and ionized species and also simple molecules formed in the recombining plasma so that time resolved detection is less useful for the spark in a liquid.

The electron density of the plasma formed in water is on the order of $10^{18}$ to $10^{19}$ cm$^{-3}$ with temperatures in the range of 7000–12,000 K.

### 5 ANALYTICAL CAPABILITIES

#### 5.1 Advantages

The analytical capabilities of a method are usually specified by a set of measurable parameters called figures-of-merit. The parameters we use here are (1) the limit of detection (LOD) for an element in a specified matrix and measurement, (2) precision, and (3) accuracy. Methods of computing the LOD can be found in the literature. Here we use $\text{LOD} = 3(\text{SD})/m$ where SD is the standard deviation of replicate measurements of the element signal using the same sample and m is the slope of the linear calibration curve of element signal or referenced element signal (see section 5.2.2) vs. element concentration. Precision refers to how reproducibly an element signal or concentration can be measured and it is specified in terms of %RSD determined by repeating a measurement several times (preferably > 6), determining the average of the element signals ($S_{\text{ave}}$), and then computing $\%\text{RSD} = (\text{SD}/S_{\text{ave}}) \times 100\%$. Accuracy refers to how close the predicted concentration of an element in a sample ($C_{\text{pred}}$) is to the actual concentration ($C_{\text{act}}$). The figure-of-merit here is %Accuracy where

$$\%\text{Accuracy} = \frac{100\% \cdot |C_{\text{act}} - C_{\text{pred}}|}{C_{\text{act}}}$$

#### 5.1.1 Range of Analysis Scenarios

Because the laser spark is formed by focused optical radiation, in addition to the conventional LIBS apparatus shown in Figure 2, several different analysis scenarios can be implemented. Some of these are shown in Figure 8 and have been incorporated into instruments.

![Figure 8](image_url)
5.1.1.1 Direct Analysis This configuration, shown in Figure 2, is used for most LIBS measurements. Here a short focal length lens is used to focus the laser pulses onto the sample (solid, liquid) or into a liquid or gas to form the plasma. The plasma light can be collected using a lens which focuses the light onto a spectrograph slit or other frequency selective device (e.g. AOTF). As an alternative, a fiber optic cable can collect and transport the light to a remotely located frequency selective device, typically a spectrograph. This analysis method represents the simplest embodiment of a LIBS apparatus.

5.1.1.2 Fiber Optic Delivery With the development of improved fiber optic materials it is now possible to focus power densities on the order of MW cm\(^{-2}\) onto the end of a fiber, without damage, and inject and then transport tens of millijoules of energy through the fiber [Figure 8a].\(^{[22]}\) By placing a lens system at the distal end of the fiber, the laser pulse can be focused to produce a spark. Transport of laser pulses over distances up to 100 meters has been demonstrated. Depending on the analysis requirements (e.g. the elements to be monitored, concentrations, etc.) the plasma light can be collected and transported back to the detection system using either the same fiber or a second fiber optic cable.

5.1.1.3 Compact Probe By combining a very compact laser with fiber optics it is possible to construct a small probe to use for remote LIBS measurements [Figure 8b].\(^{[17]}\) The laser power supply and detection system can be located remotely from the probe, connected by an umbilical cable containing electrical cables for the laser and a fiber optic cable to transport the plasma light. This configuration is used in at least one commercial LIBS unit. Compared to fiber optic delivery, this method has the advantage that spot sizes of small diameter and hence greater power density can be delivered to the target enhancing the element signal.

5.1.1.4 Stand-off Analysis Because the laser plasma is formed by focused light, it is possible to generate the laser spark at a distance on a remotely located sample [Figure 8c].\(^{[23]}\) The distances that can be achieved are a function of many parameters including the laser pulse energy and power, the beam divergence, and the optical system used to focus the pulses at a distance. With good quality components, for example, a laser plasma can be formed on soil at a distance of 19 meters using only 35 mJ pulse\(^{-1}\). In such a system, efficient collection of the plasma light is critical to obtain useful signals. Unlike the other analysis scenarios described above in which a bare fiber can be aimed at the plasma to collect sufficient light, in the case of stand-off analysis, a lens is required to increase the solid angle over which the plasma light is collected and then directed into the fiber. The light collection system can be either adjacent to or collinear with the optical axis of the system used to focus the pulses on the sample. The latter configuration is shown in Figure 8(c).

5.1.2 Minimal Sample Preparation Because of the high power densities used to form the laser spark, all types of materials can be atomized and a plasma formed in the focal region. Only optical access to the sample is required. Within the laser plasma additional atomization of ablated material continues and the resulting atoms are excited to emit light. For this reason, in general, no sample preparation is required for a LIBS measurement which is a distinct advantage compared to most other forms of analysis. For example, analysis using the ICP generally requires that the sample be chemically ashed to produce a solution that is then nebulized into the ICP plasma. Chemical preparation is a time-consuming and sometimes labor intensive process that precludes rapid sample analysis. Using LIBS however, a measurement can be carried out immediately merely by focusing the laser pulses directly on the sample.

5.1.3 Speed of Analysis LIBS measurements can be carried out in what is considered real-time because of the lack of sample preparation and the simplicity of the method which make it amenable to deployment in the field. Due to the short lifetime of the plasma (few tens of microseconds), the time required to record a spectrum is less than 100 milliseconds and using automated instrumentation driven by computer software, the analysis of the resulting spectrum is immediate. In this case, the main factor determining the speed of a measurement is the number of laser shots required to obtain a representative spectrum. Many shots may be needed to:

(1) obtain an average composition reading due to compositional inhomogeneity of the sample;

(2) ablate away an overlying surface layer having a composition that may not be representative of the underlying bulk material;

(3) average out shot-to-shot variations in the plasma characteristics.

The use of multiple pulses to overcome sampling problems associated with (1) and (2) above is obvious and is discussed in section 5.2.1. Advantages to be gained from using many laser shots in the analysis of even a uniform sample when plasma characteristics are changing shot-to-shot can be demonstrated by performing
replicate measurements, each consisting of 50, 200, and 1600 laser pulses, and then computing the precision of the measurements. For uranium in solution, the results obtained in one set of measurements were 13.3, 7.2, and 1.8% RSD, respectively. These measurements were carried out with repetitive laser plasmas formed on the surface of a liquid in which the lens-to-sample distance and hence plasma characteristics changed on each shot due to strong pressure waves generated at the liquid surface. The strong dependence of precision on the number of averaged laser pulses demonstrates the advantage of repetitive measurements.

LIBS measurements made using uniform geological samples (i.e. certified reference materials such as those available from the National Institute of Standards and Technology), metals, and liquid samples indicates that 100 laser shots can produce measurement precision on the order of 10%.

5.2 Considerations in the Use of Laser-induced Breakdown Spectroscopy

5.2.1 Sample Homogeneity

One of the more appealing aspects of LIBS is the ability to analyze samples with little or no preparation. For samples such as mixed gases and liquids containing well mixed and dissolved materials, sample homogeneity may be assumed so every plasma interrogates a small volume having a composition representative of the bulk sample. In this case, the number of laser shots to be averaged for a measurement is determined by factors such as the method of sampling and perturbations of the laser plasma. Other samples, solids in particular, cannot always be assumed to be homogeneous and, in fact, except for metals and plastics, etc. inhomogeneity should be assumed. Two types of inhomogeneity likely to be encountered are listed below.

5.2.1.1 Bulk Non-uniformity

The small area interrogated by the laser pulse represents point detection of an area of 0.1 to 1 mm diameter involving a very small mass of material (i.e. tens of nanograms, section 2.3). Surface features on rocks, for example, may display visual irregularities in the distribution of materials that are on the order of the area sampled on each shot. These non-uniformities may be averaged out using a number of laser plasmas to repetitively interrogate a sample with the results then averaged.

5.2.1.2 Non-representative Surface Composition

Some samples, such as metal alloys, and rocks exposed to the elements may have a surface layer composition that is not representative of the underlying bulk composition. For example, weathered rocks usually have a desert varnish layer ranging from 30 to 100 microns thick that has a composition different from the bulk rock matrix. Depending on the laser parameters, each interrogation by the laser pulse will produce a sampling depth ranging from a few microns up to perhaps 10 to 20 microns. Therefore, to obtain a more representative analysis, repetitive sampling by the laser spark at the same location on the sample can be used to ablate away the outer layers revealing the true bulk composition underneath.

For samples that are significantly inhomogeneous either as a result of bulk or surface non-uniformity, it may be advisable to grind the samples and then press the resulting particles to produce a flat surface for analysis. Although this procedure eliminates the real-time and in-situ analysis advantages of LIBS, it still preserves analysis capability without the need for chemical ashing of the sample.

5.2.2 Matrix Effects

LIBS, as other analytical methods, displays so-called matrix effects. That is, the composition of the sample affects the element signal such that changes in concentration of one or more of the elements forming the matrix alter an element signal even though the element concentration remains constant. For example, the signals from Si in water, in steel, and in soil appear much different even though the concentration of the element is the same in all three matrices. Even for samples that are more closely allied in matrix composition such as soils and stream sediments, significant differences in signal levels are observed for elements at identical concentrations in these materials. Because the laser spark both ablates and excites the sample, these effects can be more pronounced than in other methods that require sample preparation.

Matrix effects can be divided into two kinds, physical and chemical.

Physical matrix effects depend on the physical properties of the sample and generally relate to the ablation step of LIBS. That is, differences between the specific heat, latent heat of vaporization, thermal conductivity, absorption, etc. of different matrices can change the amount of an element ablated from one matrix compared to another matrix even though the properties of the ablation laser pulse remain constant. Changes in the amount of material ablated can often be corrected for by computing the ratio of the element emission signal to some reference element known to be in the matrix at a fixed or known concentration. In this case, it is assumed that the relative ablated masses of the element and reference elements remain constant although the total mass of ablated material may change on a shot-to-shot basis. In this case, calibration is provided by using the ratio of the element signal to the signal produced by the reference element.
Chemical matrix effects occur when the presence of one element affects the emission characteristics of another element. This can complicate calibration of the technique and hence the ability to obtain quantitative results. These effects can be calibrated out of the analysis if the concentration and effect of the interfering element(s) are known but changes in the concentration of the interfering species from sample-to-sample can be a difficult correction procedure. An example of a chemical matrix effect is the reduction in emission intensity of an ionized species [e.g. Ba(II)] upon a significant increase in the concentration of an easily ionizable species in the matrix. The easily ionizable species perturbs the electron density thereby decreasing the concentration of Ba(II). In addition, there are indications that the compound form of an element [e.g. PbNO$_3$, PbCl$_2$, etc.] may result in different emission signal strengths for the same element concentrations.

Extensive work remains to be done to characterize chemical and physical matrix effects for all types of samples and to develop methods to correct for their effects and increase the quantitative ability of LIBS.

5.2.3 Sampling Geometry

In the analysis of a solid, a plasma will be formed on the surface if the power density is sufficiently high even though the distance between the sample and the lens may be different from the focal length of the lens. These changes in the LTSD can result in changes in the mass ablated as well as changes in the temperature and electron density of the plasma which in turn affect the element emission signals. Keeping the sampling geometry constant is important to achieve the best analytical results. In the interrogation of some samples, such as soil or rocks on a conveyor belt, for example, maintaining the LTSD constant may not be possible to a high degree. This can be dealt with in several ways including the use of a lens of long focal length to focus the pulses on the sample so that relative changes in the LTSD are less important or developing an active feedback system to automatically change the lens position to keep the LTSD constant. In addition, it is often possible to compute the ratio of the element emission to the emission of some reference element (e.g. Fe in steel or in soil) known to be in the sample at a fixed concentration. In this case, relative changes in both signals are the same and the ratio remains constant as described in section 5.2.2.

5.2.4 Safety

There are three areas of safety that must be considered in the use of LIBS. These are (1) the ocular hazard posed by the laser pulse, (2) the potentially lethal high voltage circuits used by the laser, and (3) the explosive potential of the laser spark for certain materials. The first two hazards are discussed at length in the industry safety standard ANSI Z136.2 to which one is referred for further information.

The lasers used for LIBS are almost exclusively typed as Class IV indicating that both eye and skin exposure should be avoided. Established safety procedures require that precautions be taken to ensure that personnel are not exposed to the laser radiation through proper administrative and engineering controls. Engineering controls include interlocks connected to an enclosure that if opened cause immediate deactivation of the laser. The safest procedure is to completely enclose the laser radiation so that operations can be carried out as if the LIBS system contained a Class I laser in which case no extraordinary safety measures are needed outside the enclosure. In most cases, it should be possible to completely enclose the laser to protect the operator against the laser light. An exception may be the stand-off sampling geometry shown in Figure 8(c). For Nd:YAG lasers of the powers normally used for LIBS measurements, the main hazard is eye exposure. Exposure of the skin should be avoided but rarely results in significant damage at the pulse energies used for LIBS. On the other hand, the use of lasers producing radiation in the ultraviolet spectral region, such as the excimer laser, can pose a significant hazard to the skin. If interlocks must be defeated to work on an operating system or for alignment purposes, eye protection is easily provided for by the use of goggles appropriate for the laser wavelength in use.

The high voltages used by all lasers represent a lethal hazard that is most easily avoided by operating the laser with all interlocks to electrical circuits maintained in place. Only qualified personnel should be permitted to work on the high voltage power supplies in either an energized or non-energized configuration. Industry procedures such as lockout/tagout are called for in many cases involving work on electrical systems of this magnitude.

The laser plasma, as any other type of plasma source, has the potential to ignite flammable gases or to cause detonation of explosives. For this reason, the environment in which LIBS measurements will be carried out must be evaluated regarding this risk.

5.3 Representative Figures-of-merit

Because LIBS analyzes a sample directly with little or no preparation, the analytical figures-of-merit of the method are strongly dependent on sample characteristics. Listed in Table 2 are some representative LOD values for elements in different matrices. For gases, liquids, and solids the detection limits are in units of ppm.

(parts-per-million wt wt$^{-1}$) whereas for materials on filters, the LOD values refer to a surface detection limit with units of mass per surface area.

6 HYBRID TECHNIQUES

6.1 Double-pulse Techniques

A typical LIBS measurement is made by repetitively sampling a surface with a specified number of laser pulses and then averaging the element signals together. The time separation between the repetitive pulses, determined by the maximum repetition rate of the laser, is large compared to the lifetime of the plasma. This type of measurement is carried out using the RSS (repetitive single sparks) method, defined as such when the time separation between laser pulses is so large (e.g. of 1 ms) that interpulse effects are negligible. The RSS method is used most widely for both field and laboratory LIBS analyses. However, in some cases, the element signal
can be strongly enhanced by the use of a technique termed RSP (repetitive spark pair).\(^{19}\) The RSP method is defined as interrogation of a target by dual laser pulses having a time separation on the order of tens of microseconds or less so that some interpulse effects are present. An interpulse effect is defined as some effect induced by the first pulse of the pulse pair that still resides in the focal volume interrogated by the second pulse. An example is ablated material from the first pulse still residing in the focal volume during formation of a plasma by the second pulse of the pulse pair. In general, the dual pulses of the RSP are focused by the same optical elements so the focal volumes of the two pulses are coincident.

The timing between the laser pulse(s) and the gate pulse to the detector for the RSS and the RSP techniques is shown in Figure 9. Here \(\Delta T\) is the time between pulses of the RSP. In the analysis of metals, the greatest enhancements were observed for \(\Delta T\) of about 5 \(\mu\)s.\(^{27}\) In the RSS technique, the time delay \(T_d\) is referenced to the single pulse used to excite the sample at the laser repetition rate. In an RSP measurement, the parameters \(T_d\) and \(T_b\) are referenced to the second pulse of the pulse pair as shown. For soil and metal samples at atmospheric pressure, when identical timing parameters \(T_d\) and \(T_b\) were used to compare the RSS to the RSP, enhancements in element signals up to factor of 15 were obtained. The mechanism responsible for the signal enhancement seen with the RSP in these cases is that the first laser pulse ablates particles into the focal volume of the second pulse that can then more efficiently excite the ablated material.

Another use of the RSP is in the analysis of a bulk metal surface under water.\(^{28}\) Using the RSS, no element signal is obtained as shown in Figure 9(b). However, interrogation of the metal using the RSP results in the appearance of a strong spectrum shown in Figure 9(d). The reason for the enhancement is that a large bubble is formed on the metal surface by the first pulse allowing the second pulse to form inside the bubble creating conditions similar to an analysis conducted in air. The cavity created from the first pulse depends upon laser energy but is typically about 8 mm in diameter.

### 6.2 Combined with Other Methods

The use of the laser spark alone as an analytical technique has been discussed above. The ability of the laser pulse to ablate a wide range of materials resulting in atomized material has led to its combining with other analytical techniques. In most combined techniques, the laser spark serves to introduce the sample to the other technique in a vaporized form. This introduction of the vaporized sample eliminates the time-consuming sample preparation step allowing for rapid analysis. Another useful characteristic is that the vaporized sample material can be transported in a gas stream to a desired location. In this case, analysis of a large specimen can be completed without having to introduce the large sample into the analytical equipment since the laser spark ablates only a few nanograms of material. Furthermore, all types of solid materials can be introduced.

The first of the techniques discussed here is that of the laser microprobe with cross excitation referred to earlier (section 3.5.1).\(^{16}\) This technique was developed
in 1962 and is the oldest laser plasma analytical device. A typical microprobe apparatus is shown in Figure 6. A laser pulse is focused onto the sample surface using a microscope objective. A collinear visual imaging system is incorporated into the instrument design to allow for accurate sample placement under the laser pulse. Directly above the sample surface is a pair of electrodes used to excite the ablated material. The light from the electrical discharge is transmitted to the spectograph.

While the light from the laser plasma alone can be used to make analytical determinations in the microprobe devices, the combination of the electrode spark offers some spectrochemical advantages. The spark produced between the electrodes is more intense than the laser spark by a factor of 100 to 1000 times. This results in greater element emission line intensities resulting in greater sensitivity over the excitation provided by the laser spark alone. Also, because the electron density of the electrode spark is lower than that of the laser spark, the line widths are narrower and are less likely to be self-reversed. A third advantage of using the coupled technique is that the electrode spark does not contain as strong a broadband background continuum light.

The laser microprobe with cross excitation has been applied to a greater variety of materials than any other laser plasma-based method. The list of samples analyzed includes minerals, ceramics, glasses, biological materials, oils, crystals, alloys, powders, and geologic materials. The absolute detection capabilities depend on the element and the sample matrix. Typical mass detection limits for many elements lie in the range of 0.1 pg to 500 pg and concentration LOD values range from 10 ppm to 500 ppm for most elements. The laser microprobe with cross excitation is a well-researched technique and several disadvantages have become evident when compared to other analytical techniques. Since the method uses an electrode spark, the disadvantages associated with electrodes are present such as possible interference from the electrode material and wear of electrodes with use. However, the most important drawback of this technique is poor measurement precision. Typically around 25–40% RSD. Although creative attempts have been made to increase precision, the best achievable precision lies in the range of 3.6 to 16% RSD.

Laser-induced fluorescence (LIF) has been used to probe the atomic constituents of the laser plume. In LIF, the free atoms of interest are electronically excited using a dye laser pulse tuned to a specific atomic transition. The relaxation of the excited species produces fluorescence. The geometry of a typical laser ablation/LIF set-up is shown in Figure 10. Some advantages of this method compared to monitoring the plasma light directly include (1) greater concentration and absolute mass detection sensitivity, (2) fewer matrix effects, (3) wider dynamic range, and (4) isotope selectivity.

In one study, Cr was analyzed from steel, flour, and skim milk powder. The calibration curves were linear over 10 ppm to 1000 ppm and no chemical matrix effects were observed. The detection limit for Cr was determined to be 1 ppm corresponding to 0.1 pg of atomized Cr. The uncertainty in the measurements was 20–30% but was attributed to correctable experimental difficulties. Foremost was Mie scattering of the laser radiation from ablated particles in the laser plasma. This can be corrected by using filters to block the laser wavelength if the fluorescence is shifted from the laser wavelength or in the case of resonance fluorescence, by time gating the fluorescence detection. The effects of atmosphere, pressure, and time delay all have an effect on the analytical capabilities of this technique. At lower pressures, the longer lifetimes of the free atoms allow for greater resolution in time gating when resonance fluorescence is being detected.

6.3 Continuous Optical Discharge

The plasma formed by a laser pulse has a relatively low duty cycle (10⁻⁶) given that the plasma lifetime is only about 20μs and a typical laser repetition rate is 20 Hz. It is possible to generate a continuously operating laser plasma, called the continuous optical discharge (COD), by focusing a cw-CO₂ laser beam into air or another gas. Whereas typically megawatts of pulsed energy are required to form the pulsed laser plasma, only hundreds or a few thousand watts are required to form the COD. The primary reason for this is that absorption of the incoming laser energy by the plasma is proportional to the square of the laser wavelength making the power requirements of the long wavelength CO₂ laser (10600 nm) a factor of 100 less than would be required using the 1064 nm wavelength of the Nd : YAG laser. Even though the CO₂ laser provides sufficient power to sustain the COD, a pulsed laser or other method of introducing a spark into
the focal volume of the CO$_2$ laser is needed to initiate the COD. A diagram of a cell used to generate the COD is shown in Figure 11.

The laser power required to sustain the COD depends on several factors including type of gas, pressure, and quality of the laser beam. For Xe gas, which has a comparatively low ionization potential, 20 W are needed to sustain the COD at a pressure of 10 atm. While in air, which contains molecules and hard to ionize species, 2 kW are needed to maintain the plasma. For a given laser power, the COD can only be sustained over a certain pressure range for a specific gas. For instance, using a 45 W CO$_2$ beam in Xe, the operating pressures were between 1.8 atm and 4.2 atm.

The plasma temperature and electron density depend upon the operating parameters and the gas used. For a CO$_2$ laser power of 45 W, the temperature of the COD sustained in Ar at 16 atm was 13 000 K. The temperature of the COD increased to 18 000 K when a pressure of 2 atm in Ar was used. The type of gas greatly affects the plasma temperature as temperatures as high as 30 000 K have been measured in 5 atm of He. While the temperature is highly dependent on the gas and the pressure, the electron density is somewhat less variant and is typically in the range of $10^{17}$ to $10^{18}$ cm$^{-3}$.

The analytical capabilities of the COD are most easy to evaluate for analytical gas samples because these are easily introduced into a high-pressure gas cell. A linear relationship of the calibration curves for many gases has been demonstrated over several orders of magnitude. However, there seems to be an upper limit on the concentration of the analytical gas that the COD can tolerate without extinguishing. Also, some analytical gases absorb at the wavelength of the CO$_2$ beam resulting in a significant change in the excitation parameters of the COD. Another problem is that some gases have decomposition products that coat the optical elements used to form the COD. To compensate for these problems, the COD should operate as a plasmatron in which the gases are flowed through the laser beam focus and carried away without effect on the COD. Although the COD may be best suited to analyze gases, solids can be introduced into the COD via laser ablation. In conjunction with the gas stream formerly mentioned, solid samples can be ablated and carried into the COD for analysis. This process has yielded semi-quantitative analytical results using thin coatings of solid samples on a metal substrate ablated with a Nd: YAG laser pulse. Although spectrochemical analysis with the COD is possible, further development is needed to devise a method to reproducibly introduce samples into the COD without perturbing the plasma characteristics.

## 7 PERSPECTIVE AND FUTURE DEVELOPMENTS

The LIBS technique has been under investigation for almost four decades. Practical application of the method has been concurrent with much fundamental work aimed at characterizing and understanding the laser plasma and laser ablation. A variety of systems have been investigated and in some cases the processes are well understood. In other areas, much work remains. The realization of LIBS instrumentation has a less successful history. Although the laser microprobe as a laboratory instrument was offered commercially, the technology has fallen into disuse being displaced by more capable analytical methods meeting the increasing needs for better analytical results including highly sensitive detection. In the setting of an analytical laboratory, where sample preparation and the size of an instrument are not of significant concern, LIBS does not appear to have a viable role. In recent years there has been a resurgence of interest in the technology, however, for a variety of reasons the most notable of which has been environmental regulation. Often such measurements must be performed outside the laboratory in less than ideal conditions not suitable for more conventional instrumentation. In addition, often such measurements do not require the high accuracy and precision characteristic of conventional methods. In these cases, LIBS may have something to offer. Because of the simplicity of the method, the lack of sample preparation, and the non-invasive nature of the sampling step, LIBS may be the ideal technique. In addition, recent technological developments in computers, lasers, spectrographs, and detectors, resulting in rugged and compact field-portable LIBS devices, have given rise to renewed interest in the method. The activity in the
development of commercial LIBS devices over the past five years is probably greater than the combined activity over the first thirty years of the method. Whether this interest will continue and is realized on a large scale remains to be seen. What is certain, however, is that the method can uniquely meet some analysis requirements and does have a place, perhaps limited, in the arsenal of modern analytical techniques. The key to increasing these applications is a more thorough investigation and hopefully more thorough understanding of the method.

The use of microwave plasmas as radiation sources for optical atomic emission (AES), absorption (AAS) and fluorescence (AFS) spectroscopy and for laser ionization spectroscopy is treated and reference is also made to the use of microwave-induced plasmas (MIPs) as ion sources for mass spectrometry (MS). Devices for producing both single-electrode and electrodeless microwave plasmas are treated, in addition to methods for their diagnostics, and results for the analytically relevant plasma parameters are presented. Methods for sample introduction are discussed. They include dry aerosol generation techniques (hydride generation (HG), electrothermal evaporation, spark and laser ablation (LA)) and possibilities for the uptake of wet aerosols. Special reference is made to coupling with gas chromatography (GC) and also to the potential for coupling with high-performance liquid chromatography (HPLC). Further, the use of microwave plasmas for cross-excitation in the case of glow discharges (GDs) is treated. The analytical figures of merit in the case of AES with low-power microwave plasmas, single-electrode microwave plasmas, plasma torch sources and stabilized capacitively coupled plasmas are given also in the case of atomic absorption, fluorescence and laser ionization with these sources. The developments in MS in the case of both low-power and high-power microwave plasmas and in the case of various types of sample introduction are discussed.

Applications of MIP atomic spectroscopy are in the fields of biological samples with special reference to microanalysis, and of environmental samples with special emphasis on metal speciation, on-line monitoring and direct solids analysis. A critical comparison of the methodology with other methods for the determination of the elements and their species is given.

1 INTRODUCTION

For elemental determinations at widely differing concentration levels, since the 1950s plasma sources have
played an important role as radiation sources for atomic spectrometry. The latter methodology, especially in the case of optical emission spectroscopy (OES) and MS, enables many elements to be determined simultaneously in very different types of sample materials. The use of plasma sources started with the classical arc and spark sources, as known from direct solids analysis. Experiments were particularly designed aiming at a constant supply of analyte in these sources, be it for the case of liquids, finely dispersed solids or gases. This led to procedures dealing with dc plasma jets, which are still in use. Plasma atomic spectrometry in this sense, however, was hampered by the need to use electrodes for energy supply, causing blanks as a result of electrode burn-off and poor long-term stability. Therefore, there was intensive research on the availability of electrodeless discharges. Work at atmospheric pressure was found to have an important advantage, as then a number of techniques such as solution nebulization could be used easily and successfully for sample introduction into the sources. This explains the considerable attention which single-electrode microwave plasmas attracted towards the end of the 1950s, despite the fact that they were not electrodeless, as shown by papers by Mavrodineanu and Hughes \(^1\), Jecht and Kessler \(^2\) and Tappe and Van Calker \(^3\). Here plasmas were mostly produced in noble gases by the interaction of microwave energy at gigahertz frequencies with gas flows. The hot plasmas permitted efficient drying of wet aerosols, evaporation of solid particles, atomization, excitation and ionization. They were operated at a metal electrode (W, Au-coated Cu, brass) and they could be operated with Ar, He and even with air at an electrical power ranging from 200 to 600 W. The discharge has a bush form and the hottest zones are in the center of the plasma. In the case of high concentrations of alkali, however, the plasma geometry drastically changed, which led to large concomitant effects as compared with the inductively coupled plasma (ICP) \(^4\). Accordingly, these sources could be used successfully as radiation sources in atomic emission and, provided that ways are found to enter the ions in a mass spectrometer, also as ion sources for MS.

The trends in the development of plasma spectroscopy in general were reflected in regular surveys in the literature. They started with the conference proceedings of the first Winter Conference on Plasma Spectrochemistry \(^5\) and reviews on commercial instrumentation (see e.g. Broekaert \(^6\)) and on the trends in developments in plasma spectrometry (see e.g. Broekaert \(^7\)) regularly occur. Also, the *Journal of Analytical Atomic Spectrometry* updates are very informative to the field (see e.g. Sharp et al. \(^8\)).

The success of plasma atomic spectroscopy first started with the availability of the ICP, first described by Greenfield et al. \(^9\) and by Wendt and Fassel \(^10\). Here a toroidal plasma with a diameter of up to 20 mm and a height of up to 50 mm could be realized. Further, both wet and dry aerosols containing even large particulates could be entered, guaranteeing residence times of several milliseconds at temperatures above 4000 K. These sources, however, also necessitate working with gas flows higher than 10 L min\(^{-1}\) and at an electrical power in the kilowatt range, both of which make the operating costs high. Apart from the single-electrode microwave plasmas, considerable effort was put into low-pressure microwave plasmas, as they became available towards the end of the 1950s also (see e.g. Uden \(^11\)). Here excitation in sealed tubes could be used for drinking water analysis, but the analysis times were long \(^12\). The breakthrough in microwave plasmas first took place when electrodeless plasma discharges, which can be operated at atmospheric pressure, became available. This was realized in 1976 by the work of Beenakker \(^13\), who described a cavity in which both He and Ar microwave discharges could be produced with a power of up to ca. 100 W with a gas consumption of below 1 L min\(^{-1}\). These sources became very popular for the excitation of dry analyte vapors, as obtained in the electrothermal vaporization (ETV) of dry solution residues and also in GC. For the latter case, low-power electrodeless microwave discharges are now widely used.

To bridge the gap towards high-power plasmas with and without electrodes, in which wet aerosols can be taken up and where air operation is also possible, intensive research was carried out. This resulted in a wide variety of devices such as the surfatron, \(^14\) which will be discussed further, and the recent microwave plasma torch (MPT) developed by Jin et al. \(^15\) and microwave plasma atomic spectroscopy became a powerful tool for elemental analysis.

The special features of the microwave plasma itself have been the subject of several review and tutorial papers by experts in the field. Jin et al. \(^16\) reviewed work up to 1997 with 255 references. Winforder et al. \(^17\) surveyed microwave plasmas and GDs with respect to their typical lines of development. Reviews on microwave plasmas have been regularly published, e.g. for the work before 1980 by Zander and Hieftje \(^18\); in 1988 by Abdillahi \(^19\); in 1995 by Culp and Ng \(^20\); in 1984 by Matousek et al. \(^21\) and in 1990 and 1996 by Broekaert \(^22, 23\).

### 2 Devices for the Generation of Microwave Plasmas

Microwave generators operated at the allowed frequency of 2.45 GHz make use of standard technology in fields such as microwave heating and microwave sputtering.
device, whereas the development of microwave cavities and resonators and properly designed torches was and still is a field of continuous innovation, as it can be seen from reviews such as that by Goode and Baughman.\textsuperscript{(24)}

### 2.1 Microwave Generators

For the production of microwave energy, use is made of klystrons and magnetrons, the latter being the more important when a power level above ca. 100 W is required. In a magnetron (Figure 1), a filament current is amplified and flows to an annular anode, which contains a certain number of cavity resonators.\textsuperscript{(26)} Perpendicular to this plane, a very strong stationary magnetic field is applied. Through the action of the secondary cavities, an ultrahigh frequency (UHF) current with a characteristic frequency is produced, which can be coupled out with a loop and transported through a coaxial connector to a waveguide end or to a resonator. The power output of the magnetron can be regulated and must be stabilized and smoothed so as to allow, at any level, stable operation of the plasma produced. Means for converting pulsed into continuous-wave operation in generators for microwave plasmas produced. Means for converting pulsed into continuous-wave operation in generators for microwave plasma production were described by Brandl et al.\textsuperscript{(27)}

Microwave generators operating at power levels from a few watts to 1 kW with sufficient stability (ripple and drift <1%) are now commercially available. Miniaturization of microwave generators, especially with the aim of realizing small size and low power as required when generating smaller plasmas is possible through the use of transistor technology.

When transporting microwave energy into suitable structures, only part of the energy will be taken up in the device, part being reflected to the generator. The forward and reflected power can be measured with the aid of a bidirectional coupling loop. When transporting microwaves to a coaxial or cavity waveguide, the dimensions of the latter must be tuned to the wavelength of the microwave. Cavity conductors are rigid metal tubes with a rectangular or circular cross-section in which the microwaves propagate and their dimensions are standardized, e.g. for the case of 2.54 GHz, 91 mm internal width and 42 mm internal height. Individual waveguides must be tightly connected through suitable flanges to prevent microwave leakage. Each slit acts as a secondary source. Hence holes and slits for observation must be provided with a chimney so as to prevent the sorting of microwave radiation by damping. The resonance conditions required to optimize the ratio of forward to reflected power can be realized by fine tuning with stubs or replaceable walls and with screws perturbing the microwave field.

### 2.2 Cavities and Resonant Structures

A plasma can be operated at the top of the internal conductor of a waveguide. To couple microwave energy inductively into a gas, a microwave cavity or resonator is used. The waveguide then should end at a length where the microwave amplitude maximum is located, whereas a cavity consists of a closed metal tube of rectangular or circular cross-section and its internal dimensions allow the formation of standing waves. Tapered rectangular cavities, Evenson quarter-wave cavities and Broida quarter- or three-quarter-wave cavities are commonly used. Anyhow, as the plasma formed disturbs the field, fine tuning with screws and stubs is required.

At reduced pressure many cavities could be used to obtain a microwave discharge, even in the case of gas mixtures (see e.g. McKenna et al.\textsuperscript{(28)}). They include Evanson cavities and other devices. They played an important role in the excitation of analytes enclosed in quartz ampules, which was developed as a technique for dry solution residue analyses for volatile elements by OES\textsuperscript{(29\textendash}31) and especially also to element-specific detection in GC (see section 4.4).

Microwave plasmas operated at the tip of a metal electrode connected with the internal conductor were the oldest microwave structures used for plasma spectrochemical analysis. Here the analyte flows around the tip of the electrode and enters the plasma axially (Figure 2). Although this method is not optimal as the plasma has a bush form and maximum temperatures in the center lead to poorer signal-to-noise ratios (S/Ns), it found widespread use. Indeed, it is stable, can be operated with both noble and molecular gases and it even accepts wet aerosols. Attempts were made to improve the sampling capacity further by using a gas flow around the tip of the electrode to stabilize and to concentrate the analyte flow.\textsuperscript{(33)} It could be further decreased in size and in this form it still attracts interest (for the analytical figures of merit, see e.g. Wünsch et al.\textsuperscript{(34)}).
Microwave discharges first became popular when it became possible to produce them at atmospheric pressure and low power, as was first possible with the TM\textsubscript{010} resonator described by Beenakker and was improved especially with respect to coupling.\cite{35,36,37}

As shown in Figure 3, in this device a standing wave is produced in a circular cavity into which the microwave energy is entered with the aid of a loop or with the aid of the end of the inner conductor acting as an antenna. Coarse tuning can be accomplished through the positioning of the antenna and for fine tuning a ceramic stub is provided, with which distortions of the field in the cavity can be produced. The latter was found to be no longer required in the case of delivering the microwave power with the aid of a loop.\cite{39}

In this cavity the power may vary from a few tens of watts to more than 300 W, depending on a cooling of the cavity, the burner and the respective gas flows. These parameters also determine the ways of sample introduction possible and sources operated at moderate power especially were designed with the aim of taking up wet aerosols. (see e.g. Haas et al.\cite{40}).

At the end of the 1970s the surfatron was proposed as a source for analytical atomic spectroscopy. This microwave plasma, as shown in Figure 4, is produced in a microwave structure with varying depth and side-on coupling of the microwave power through the internal conductor.\cite{41}

Here, a microwave expands through the slit between the front plate and the plasma, through which a slightly hollow plasma with improved sampling capacity is realized. Selby and Hieftje\cite{42} optimized the construction of the surfatron as a device for analytical work by making it of the same dimensions as the TM\textsubscript{010} resonator according to Beenakker. The working power and pressure then become very similar to those of the resonator according to Beenakker. However, the plasma in a surfatron seemed to be more robust, e.g. when entering gases such as H\textsubscript{2} accompanying the volatile hydrides in HG work.\cite{43}
Rectangular cavities, as described by Matusiewicz, offer good possibilities for spectrochemical analysis. They can be operated from 100 W to several hundred watts. Even solvent-loaded aerosols can be entered in these sources after careful optimization. Further, the slab-line cavity described by Estes et al. is also of use, but for the excitation of gaseous substances only. The different devices described in the literature were often compared when using one sample introduction technique (in the case of HG, see e.g. Mulligan et al.) or with other plasmas also for the case of solution analysis.

2.3 Plasma Torches
The analytical features of different types of microwave discharges mainly depend on the type of torch in which they are produced. The latter especially determines the admissible power and whether a filament-type, a delocalized or a toroidal plasma can be obtained.

In Ar or He microwave discharges, up to about 80 W can easily be produced in a quartz capillary with an internal diameter of up to 1 mm, as described in the original version according to Beenakker. However, they also can be operated with cooling by an outer gas flow. Through observation of the Si lines, it could be shown that the erosion of the quartz tube can be considerable and it could be substantially decreased by using a torch where the discharge capillary is liquid cooled. This tube erosion could even be used as a technique of sample introduction, namely by supplying a liquid aliquot in the capillary of the MIP prior to initiating the discharge and ablating the dry solution residue with the aid of the discharge.

Extensive efforts have been made to produce toroidal MIP plasma sources for OES. Axial observation then enables it to obtain high signal-to-background ratios and accordingly low detection limits. Success in this respect was achieved by Kollotzek et al. by using wetted Ar and carefully centering a quartz capillary of 4 mm internal diameter in the resonator according to Beenakker. Later on it was found that such a plasma (Figure 5a) at a power of about 100 W could be obtained when the working gas only was led through a water-filled washing flask. With dry He a diffuse delocalized discharge, which homogeneously fills a quartz tube of 4 mm internal diameter, could be obtained at 100–300 W (Figure 5b). However, here the cooling of the discharge tube is much more critical.

Another approach especially makes use of special torch constructions. Here Bollo-Kamara and Coding were successful in using a dual-tube arrangement with a threaded inset, by means of which a tangential gas flow could be realized. More work on tangential flow torches included extensive diagnostic studies of hydrodynamic flows and spatially resolved temperature measurements and studies on self-centering plasmas and their use in GC detection.

For the study of different arrangements, demountable torches in a polytetrafluoroethylene (PTFE) socket are very useful, as then the individual tubes can easily be changed in position or exchanged after attack by the discharge. A detailed study and an improvement of the torch proposed by Bollo-Kamara and Coding was realized with a such demountable torch; here a PTFE gas-swirl modifier was used and also a PTFE socket for the tubes, making glass-blowing superfluous.

Further work was also done on laminar-flow plasmas with the aim of obtaining a plasma with a high discharge stability and robustness with respect to incoming analyte clouds. This is very important so as to keep baseline changes in GC detection to the minimum. It was found that because of improved stability the detection limits obtainable with laminar flow torches were considerably lower than those with tangential flow torches. It was reported that stabilities even better than 2% over 2 days could be realized.

A significant innovation in MIP work with respect to burner design was made by Jin et al. They used a concentric arrangement of two metal tubes mounted in...
an enclosure and the power was coupled in by means of the intermediate tube (Figure 6). Power coupling initially was realized with the aid of a gliding ring moving over the intermediate tube. Effective power coupling could be achieved by varying the depth of the outer enclosure and by changing the coupler position. It was found that with both Ar and He stable discharges could be realized at a gas consumption below 1 L min\(^{-1}\) and with a power of up to 200 W depending on the efficiency of the cooling. As a wide variety of sample introduction techniques could be used, this source is now one of the prominent microwave structures.

The design of the MPT was considerably improved by Pack and Hieftje.\(^{(62)}\) First, it was possible to close the adjustment slit completely, so that air no longer enters between the intermediate and the outer tubes and microwave leakages also are minimized. Further, it was possible to use a quartz instead of a metal tube as the internal tube. This considerably lowers the risks for contamination when analyzing real samples. It was also found that sheathing of the plasma with N\(_2\) greatly improved its stability. Further improvements of the torch design resulted from modeling of the electromagnetic fields without and with plasma. As a result, it was possible to design a torch which no longer requires tuning and with which ignition and stable operation of the MPT was also possible (Figure 7).\(^{(63)}\) This significantly improves the reproducibility of the device with respect to ignition and operation and makes the MPT a robust spectrochemical source. Here the internal conductor of the coaxial cable is directly connected to the coupler, which is rigidly fixed to the intermediate tube. Further, it was no longer required to use a sheathing gas in the metal part of the torch. A quartz enclosure around the plasma itself, however, was found to stabilize it considerably against air turbulence in the laboratory. Further developments include pulsed operation of a microwave discharge at higher power (500 W) and its coupling with spark ablation (SA) sampling devices.\(^{(64)}\)

High-power inductively coupled microwave plasmas could be operated in various MIP resonant structures. This first is possible in the TM\(_{010}\) resonator according to Beenakker where, at powers of up to 500 W, Ar, He and air plasmas can be obtained, again by using modular
cooled torches. Such devices were often compared in the case of well-defined sampling techniques such as GC detection.

Another possibility is the use of ICP-like torches in a rectangular cavity (Figure 8). Here a power up to the kilowatt range can be used and at several liters per minute gas consumption a very stable plasma can be obtained with Ar and also with air. This MIP is a powerful source for AES and for MS.

3 DIAGNOSTICS OF MICROWAVE PLASMAS

The diagnostics of microwave plasmas deal with both the measurements of the plasma physical properties, including the flow dynamics, temperatures and particle number densities, and their spectroscopic properties with respect to optical emission, absorption and fluorescence, their properties as atom reservoirs and their properties as ion sources. The results obtained here differ for the different types of microwave discharges used for spectrochemical purposes; however, some trends are common.

As long as MIPs at atmospheric pressure are considered, the plasma is near to thermal equilibrium (TE); however, there might already be much greater differences between the different temperatures than in the case of the ICP. The main processes taking place in the plasma are as follows:

- electron impact for the excitation of working gas species (Equation 1):
  \[ A + e \rightarrow A^* \] (1)
- electron impact for the ionization of working gas species (Equation 2):
  \[ A + e \rightarrow A^+ \] (2)
- electron impact for the excitation of analyte species (Equation 3):
  \[ S + e \rightarrow S^* \] (3)
- electron impact for the direct ionization of the analyte species (Equation 4):
  \[ S + e \rightarrow S^+ \] (4)
- radiative recombination (Equation 5):
  \[ A^* \text{ or } S^* + e \rightarrow A \text{ or } S + h\nu \] (5)
- excitation of analyte through collisions with excited working gas atoms (Equation 6):
  \[ S + A^* \rightarrow S^* + A \] (6)
- ionization of analyte through collisions with excited working gas atoms (Equation 7):
  \[ S + A^* \rightarrow S^+ + A \] (7)

A special case is excitation through collisions with metastable noble gas species (Ar\textsuperscript{m}). These are species for which a decay through the emission of radiation is forbidden as the multiplicity of the lower states differs from that of the excited states. As the energy of these species is high (e.g. Ar\textsuperscript{m} in 11.7 eV, He\textsuperscript{2+} in 14.6–17.4 eV and He\textsuperscript{2+} in 18.8–21.6 eV), this process may be relevant for the one-step excitation of ion lines and it is highly selective.

- Charge-transfer processes (Equation 8):
  \[ A^{(+\ast)} + S \rightarrow A + S^{(+\ast)} \] (8)
- radiation trapping (Equation 9):
  \[ A + h\nu \rightarrow A^* \] (9)

may be important for energy exchange and excitation as well.

With respect to diagnostics, many papers have described the determination of excitation temperatures from the relative intensities of atomic emission lines originating from the same stage of ionization. The intensity of an atomic emission line \( I_{qp} \), corresponding with a transition from the higher level \( q \) to the lower level \( p \), is proportional to the population of the atoms \( a \) in level \( q \) (\( n_{aq} \)) and is given by Equation (10):

\[
I_{qp} = A_{qp} n_{aq} h\nu_{qp}
\]

After substitution of the population of the excited level according to Boltzmann’s equation (Equation 11):

\[
\frac{n_{aq}}{n_a} = \left( \frac{g_q}{Z_a} \right) \exp \left( \frac{-E_q}{kT} \right)
\]

where \( n_a \) is the total density of atoms \( a \) over all levels, \( g_q \) the statistical weight of the excited level \( q \), \( Z_a \) the partition function for the atoms (being a function of the temperature), \( E_q \) the excitation energy for the excited level \( q \) and \( T \) the excitation temperature (often denoted \( T_{ex} \)), one obtains Equation (12):

\[
I_{qp} = A_{qp} h\nu_{qp} n_a \left( \frac{g_q}{Z_a} \right) \exp \left( \frac{-E_q}{kT} \right)
\]
\( T \) then can be determined from the intensity ratio for two lines (a and b) with wavelength \( \lambda_a \) and \( \lambda_b \) of the same ionization state of an element according to Equation (13):

\[
T = \frac{5040(V_a - V_b)}{\log[(gA)_a/(gA)_b] - \log(\lambda_a/\lambda_b) - \log(I_a/I_b)}
\]  

(13)

Often the line pair Zn 307.206/Zn 307.59 nm is used. This line pair is very suitable because ionization of zinc is low as a result of its relatively high ionization energy. Also, the wavelengths are close to each other, which minimizes errors introduced by changes in the spectral response of the detector, and the ratio of the \( gA \) values is well known.

The excitation temperatures can also be determined from the slope of the plot of \( \log[I_{ap}/(gA_{qp})] \) versus \( E_{aq} \), which is \(-1/kT\). The \( \lambda/gA \) values for a large number of elements and lines are available. Spectroscopic measurements of temperatures from line intensity ratios may be hindered by deviations from thermodynamic behavior in real radiation sources and by inaccuracies in the transition probabilities. The determination of excitation temperatures in spatially inhomogeneous plasmas, which have a cylindrical symmetry, can be performed with the aid of Abel inversion, as treated extensively in classical textbooks on atomic spectroscopy (see e.g. the book by Boumans (70)).

For the measurement of the gas kinetic temperatures, both measurements of the rotational temperatures from the band spectra of species such as the OH radical or the N\(_2^+\) ion and measurements of Doppler widths have been proposed. In the first case one makes use of the rotational fine structure of the vibration bands.

Molecules or radicals have various electronic energy levels (\( ^1\Sigma, ^3\Sigma, ^2\Pi \), etc.) which have a vibrational fine structure (\( \nu = 0, 1, 2, 3, \ldots \)), and these levels, in turn, have a rotational hyperfine structure (\( J = 0, 1, 2, 3, \ldots \)). The total energy of a state may be written as Equation (14):

\[
E_i = E_{el} + E_{vib} + E_{rot}
\]  

(14)

\( E_{el} \) is of the order of 1–10 eV, the energy difference between two vibrational levels of the same electronic state is of the order of 0.25 eV and the separation of rotational levels is of the order of 0.005 eV. When the rotational levels considered belong to the same electronic level, the emitted radiation is in the infrared (IR) region. When they belong to different electronic levels, they occur in the ultraviolet (UV) or visible (VIS) region. Transitions are characterized by the three quantum numbers of the states involved: \( n', \nu', j' \) and \( n'', \nu'', j'' \). All lines which originate from transitions between rotational levels belonging to different vibrational levels of two electronic states form the band: \( n', \nu' \rightarrow n'', \nu'' \). For these band spectra, the selection rule is \( \Delta j = j' - j'' = \pm 1, 0 \). Transitions for which \( J'' = j'' + 1 \) give rise to the P-branch, \( J'' = j'' - 1 \) to the R-branch and \( j'' = j'' \) to the Q-branch of the band. The line corresponding to \( j' = j'' = 0 \) is the zero line of the band. When \( \nu' = \nu'' = 0 \) it is also the zero line of the system. The difference between the wavenumber of a rotational line and the wavenumber of the zero line in the case of the P- and the R-branch is a function of the rotational quantum number \( j \) and the rotation constant \( B_{el} \), for which (Equation 15):

\[
\frac{E_i}{kT} = B_{el}j(j + 1)
\]  

(15)

The functional relation is quadratic and known as the Fortrat parabola.

As in the case of atomic spectral lines, the intensity of a rotational line can be written as Equation (16):

\[
I_{nm} = \frac{N_mA_{nm}h
u_{nm}}{2\pi}
\]  

(16)

where \( N_m \) is the population of the excited level and \( \nu_{nm} \) the frequency of the emitted radiation. The transition probability for dipole radiation is given by Equation (17):

\[
A_{nm} = \frac{64\pi^4v_{nm}^3}{5k} \frac{1}{g_m} \sum |R_{nmk}|^2
\]  

(17)

where \( i \) and \( k \) are the degeneracies of the upper (m) and the lower state (n). \( R_{nmk} \) is a matrix element of the electrical dipole moment and \( g_m \) is the statistical weight of the upper state; \( N_m \) is given by the Boltzmann equation (see Equation 11) where the energy to be included is \( E_i \) (see Equation 15) with \( j = j' \), being the rotational term of the upper level. For a \( ^2\Sigma_g-^2\Sigma_u \) transition, between a so-called “gerade” (g) and “ungerade” (u) level, the term \( \Sigma |R_{nmk}|^2 = J' + J'' + 1 \), where \( J' \) and \( J'' \) are the rotational quantum numbers of the upper and lower state. Accordingly (Equation 18):

\[
I_{nm} = \frac{16\pi^3cN_{nm}v_{nm}^4}{3Z(T)} \left( J' + J'' + 1 \right) \times \exp \left( \frac{-hcB_{el}J'(J' + 1)}{kT} \right)
\]  

(18)

or

\[
\ln \frac{I_{nm}}{J' + J'' + 1} = \ln \left( \frac{16\pi^3cN_{nm}v_{nm}^4}{3Z(T)} \right) - \frac{hcB_{el}J'(J' + 1)}{kT}
\]  

(19)

By plotting \( \ln[I_{nm}/(J' + J'' + 1)] \) versus \( J'(J' + 1) \) for a series of rotational lines, a so-called rotational temperature can be determined from the slope. It reflects the kinetic energy of neutrals and ions in the plasma. For the determination of the gas kinetic temperatures, both measurements of the rotational temperatures from the band spectra of species such as the OH radical or the N\(_2^+\)
ion as well as measurements of Doppler widths have been used. For the measurements of electron temperatures Thomson scattering has also been used.\(^{\text{71}}\) The basics of these methods are described in classical textbooks\(^{\text{70,72}}\) and papers.\(^{\text{73}}\) Also, efforts have been made to describe the flow dynamics of microwave discharges, which especially were found to be very useful for improving the design of microwave structures used for spectrochemical analysis.\(^{\text{63}}\)

### 3.1 Low-power Microwave-induced Plasmas

In early MIP work, Beenakker MIP\(^{\text{69}}\) mentioned that the electron temperatures in an MIP operated in a TM\(_{010}\) cavity should be high whereas rotational temperatures, being a good approximation to the gas kinetic temperatures, as described by Heltai et al.,\(^{\text{52}}\) are only of the order of 1500 – 2400 K (Figure 9a and b) both for He and Ar MIPs. Similar measurements were made in the surfatron plasma,\(^{\text{74}}\) in the modulated surfatron\(^{\text{75}}\) and also in MIPs operated in CO\(_2\) and in He.\(^{\text{76}}\) For the case of a surfatron the electromagnetic properties were studied\(^{\text{77}}\) in addition and also their fundamental parameters.\(^{\text{78}}\) In the case of the MIP the importance of charge transfer was shown by Brandl and Carnahan.\(^{\text{79}}\) The diagnostic data are important for the dissociation of molecular species, being especially studied with respect to combinations of chromatography and MIP excitation, as described for hydrocarbons.\(^{\text{80}}\)

Diagnostics have been performed not only for some widely used types of MIPs but also for a low-power Ar MIP used for the analysis of solutions\(^{\text{81}}\) and for an MIP operated in a liquid-cooled discharge tube.\(^{\text{82}}\) Studies on the energetic balance in low-pressure MIPs have also been made.\(^{\text{83}}\) With special plasmas, such as a low-density He electron cyclotron resonance microwave plasma, techniques for temperature measurements, e.g. with line broadening, have been developed.\(^{\text{84}}\)

In addition to plasma parameter measurements, noise analysis of the reflected power of MIPs,\(^{\text{85}}\) near-infrared (NIR) characteristics of MIPs with respect to the determination of nonmetals\(^{\text{86}}\) and studies on MS of MIPs\(^{\text{87}}\) were also performed.

### 3.2 Single-electrode Plasmas

For single-electrode plasmas, electron number densities and excitation temperatures were determined by Kirsch et al.,\(^{\text{88}}\) who had already extensively used this plasma for analytical purposes (see e.g. Hanamura et al.\(^{\text{89}}\)), as did Boumans et al. (see e.g. Boumans et al.\(^{\text{41}}\)). Here excitation temperatures of 5000 – 7000 K were reported for a 500 W capacitively coupled microwave plasma (CMP) operated in Ar or He with N\(_2\) as wall-stabilizing

---

**Figure 9** (a) Radial intensity profiles of a toroidal Ar MIP. Discharge tube: external diameter 7 mm, internal diameter 5 mm; P= of H\(_2\)O or of a 100 \(\mu\)g mL\(^{-1}\) solution of copper, –100 W. (b) Radial intensity profiles measured for a cylindrical He MIP. Discharge tube: external diameter 7 mm, internal diameter 5 mm; 0.2 L min\(^{-1}\) helium; without aerosol introduction, –150 W. (c) He 388.7 nm; (●) (0, 0) N\(_2^+\) band head at 390 nm; ( ) (0, 0) OH band head at 306 nm.\(^{\text{52}}\)
not differ much from these obtained by Kirsch et al. performed. As shown in Table 1, these temperatures did with air only could be measured and tomographic studies each other. The plasma temperatures for CMPs operated rotational temperatures measured then came nearer to be shown to thermalize the plasma, as excitation and or Na is added (Figure 10). Ethanol addition could also of ambipolar diffusion and becomes broader when Cs could be shown that the plasma blows up as a result of using both He and Ar as working gases made it a torch and that the moderate power and the possibility a toroidal structure can be operated in an ICP-like MPT, it became clear that a microwave plasma with Since the first publications by Jin et al. 3.3 Plasma Torch Discharges

Since the first publications by Jin et al. on the MPT, it became clear that a microwave plasma with a toroidal structure can be operated in an ICP-like torch and that the moderate power and the possibility of using both He and Ar as working gases made it a very powerful atomic spectrometric source. This MIP could be well operated in combination with flow-cell HG. There was no need to remove the excess of H2 produced before leading the reaction gases, including H2 and the hydrides, into the plasma, which was found to be impossible with an MIP according to Beenakker. From noise power spectra obtained with the MPT in the case of HG, as shown in Figure 11(a) and (b), it was found that even with an excess of H2 the frequency component stemming from the plasma swirl still is the important one, as it is in the case of the ICP. Further, however, flicker noise was found to occur at frequencies of 0.2–0.5 Hz and white noise was found to dominate below 100 Hz. Temperatures were also measured in the microwave plasma operated in the MPT. For electron and gas kinetic temperatures, values at different heights in the plasma were obtained by Thomson scattering. A complete temperature and electron number density mapping in the case of a modified MPT was performed recently. It showed that in the case of wet plasmas the electron temperature increased similarly as in the case of the ICP. Further, mappings of the rotational temperatures, as possible with a charge-coupled device (CCD) spectrometer, were performed by Engel et al. They showed that the rotational temperature in the

gas. The flow pattern changes as the result of the addition of the alkali metals, as reflected in the tomographic studies reported by Bings and Broekaert.

Figure 10 Mapping for excitation temperature ($T_{\text{exc}}$) in an air CMP. Here it could be shown that the plasma blows up as a result of ambipolar diffusion and becomes broader when Cs or Na is added (Figure 10). Ethanol addition could also be shown to thermalize the plasma, as excitation and rotational temperatures measured then came nearer to each other. The plasma temperatures for CMPs operated with air only could be measured and tomographic studies performed. As shown in Table 1, these temperatures did not differ much from these obtained by Kirsch et al. with noble gases and neither did the electron number densities or the rotational temperatures. Anyhow, it could be shown that CMPs, despite the fact that they are often operated at a power of 500W which is near to the power of low-power analytical ICPs, have a larger deviation from local thermal equilibrium (LTE) than the ICP. This can be understood from the higher operational frequencies of microwave discharges, which even more hamper energy exchange as compared with the ICP.

Figure 11 Effect of H2 addition (13.5 mL min$^{-1}$) on the noise spectra of the He I 501.56 nm line at different heights above the top of the torch.
MPT increases with the water uptake, which might even improve the robustness of the source. This may explain why it easily seemed to be possible to take up water
and even acetonitrile-loaded aerosols into the MPT, as described by Prokisch and Broekaert.\(^{97}\)

Also for other types of MIPs, spatial mappings of analyte intensities and plasma parameters were made as an aid in optimization studies.\(^{98}\) Further, studies were not confined to noble gas plasmas, but also plasma torches obtained in the case of \(\text{N}_2\) at a higher power were operated in a TM\(_{010}\) resonator.\(^{99}\) These devices turned out to be of use for solution analysis and could use an ICP-like torch. This discharge, as well as that referred to by Ohata and Furuta\(^{100}\) and later proposed as a source for MIP/MS, is similar to that described by Leis and Broekaert.\(^{67}\)

This plasma has a toroidal shape, it can take up water-loaded aerosols and it can be operated with both molecular and noble gases.

For this plasma it has been reported that the Saha equation applies. This equation describes the ionization in a thermal plasma as (Equation 20):

\[
S_{pi}(T) = \frac{p_{i}p_{e}}{p_{a}} = \frac{(2\pi m)^{3/2}(kT)^{5/2}}{h^{3}(2Z_{i}/Z_{a})}[\exp(-E_{i}/kT)]
\]

(20)

where \(S_{pi}\) is the Saha function expressed in terms of the partial pressures for the component \(j\), \(p_{i}\), \(p_{e}\) and \(p_{a}\), are the partial pressures for ions, electrons and atoms, respectively, the factor 2 is the statistical weight of the free electron (two spin orientations), \(m\) is the mass of the electron \((9.11 \times 10^{-28}\ \text{g})\), \(k\) is the Boltzmann constant \((k = 1.38 \times 10^{-23}\ \text{J} \cdot \text{K}^{-1})\), \(T\) is the absolute temperature (K), \(h\) is Planck’s constant \((h = 6.62 \times 10^{-34}\ \text{J} \cdot \text{s})\), \(Z_{i}\) and \(Z_{a}\) are the partition functions of the ions and the atoms of the element \(j\), respectively, and \(E_{i}\) is the ionization energy of the element \(j\). As 1 eV = 1.6 \times 10^{-19}\ J, this leads to Equation (21):

\[
\log S_{pi} = \frac{5}{2} \log \frac{T - 5040}{T} V_{ij} + \log \left( \frac{Z_{i}}{Z_{a}} \right) - 6.18
\]

(21)

where \(V_{ij}\) is the ionization energy (eV). It should be mentioned, however, that the Saha equation is only valid for plasmas in LTE, which strictly does not apply in the case of many MIPs. The latter is understandable from the fact that the light electrons can easily take up energy at microwave frequencies, but heavy ions much less so. This results in different kinetic energies and different temperatures for the light electrons and the heavy ions and, accordingly, in departures from LTE. By Thomson scattering, the electron temperature can be determined irrespective of whether the plasma is in LTE or not and for the TIA, for instance, electron temperatures in the case of \(\text{Ar}\) were reported to be of the order of \(>8700\ \text{K}\).\(^{71}\) This was the case even for a \(\text{He}\) plasma operated in air.\(^{102}\)

4 SAMPLE INTRODUCTION

As in any spectrochemical source, the analyte has to be brought as an atomic cloud in the zones where excitation and/or ionization takes place. Because of the relatively low gas kinetic temperatures in the microwave discharges, their atomization capacity is not as high as in the ICP, which is generally operated at higher power than microwave discharges. Accordingly, the analyte must be atomized more efficiently or at least it must be present in a very fine form before it enters the microwave plasma.

4.1 Techniques for Sample Introduction

Sample introduction is the “Achilles’ heel” of plasma spectrochemical analysis\(^{103,104}\) and many techniques which can be used in the case of microwave plasmas have been described in the plasma spectrometry literature, as shown in a monograph by Sneddon,\(^{105}\) a special issue of Spectrochimica Acta, Part B,\(^{106}\) and various reviews treating aspects such as flow injection,\(^{107}\) coupling techniques,\(^{108}\) on-line separation\(^{109}\) and sample introduction in atmospheric pressure MIPs\(^{110}\) or MIPs in general.\(^{111,112}\) These techniques include PN, ultrasonic nebulization (USN), ETV of microsamples, HG for the elements having volatile hydrides and direct solids sampling methods such as slurry nebulization, SA and LA and direct sample insertion, as are well known from the ICP literature (Figure 12). In the case of microwave plasmas at low power, especially techniques where a dry atom cloud is formed will be favorable. This explains, why tandem systems using an MIP for the excitation of the exhaust aerosols of an ICP were of use,\(^{114}\) in which the MIP even could be operated at reduced pressure.\(^{115}\)

4.2 Sample Introduction in Low-power Microwave Plasmas

In the case of very weak discharges such as the MIP according to Beenakker, especially ETV and HG\(^{116}\) have been used for sample introduction. In the case of ETV, as reviewed by Matusiewicz,\(^{117,118}\) different types of electrothermal devices can be used. They include...
The technique could be used for the determination of I in a commercial graphite furnace (GF) as known from AAS\(^{119-121}\) as well as a graphite rod atomizer,\(^{122}\) even for the case of a low-pressure MIP,\(^{123}\) wire-loop devices entered into a microtube\(^{124,125}\) and Ta boat\(^{126}\) and Ta strip devices.\(^{127}\) In the case of the resonator according to Beenakker, it could be shown that the detection limits with GF sample evaporation can be considerably improved by using a toroidal instead of a filament discharge.\(^{120}\) Special attention was also given to the acquisition of the transient signals, for which a rapid scanning monochromator can be very helpful.\(^{128}\) The technique could be used for the determination of I in HCl,\(^{129}\) for the determination of nonmetals in the case of an He discharge,\(^{130,131}\) for the determination of S,\(^{132,133}\) of halogenated compounds\(^{134}\) and of Zn\(^{135}\) and for the determination of Ni and Pb in bones.\(^{136}\) A useful way to increase further the detection power of ETV coupled to OES with the MIP consists of preconcentration of the trace elements to be determined by electrolysis on a graphite tube filled with vitreous C, as shown for the case of Pb.\(^{137}\) Chromatography on a vitrified C-filled column can also be used for this purpose.\(^{138}\) Many phenomena, however, still have to be studied, such as the aerosol transport mechanisms\(^{139}\) and also vaporization at low pressure. The latter, for example, has been studied for the case of chlorides, sulfates and nitrates.\(^{140}\) Special ETV techniques may also make use of moving bands.\(^{141}\)

The generation of hydrides and of other volatile compounds has found widespread use in MIP work. In a number of cases, however, the vapors generated have to be freed from an excess of molecular gases such as H\(_2\) or even water vapor, as these species may change the plasma impedance so much that the circuit leaves the resonance frequency and the plasma is extinguished. In the case of a surfatron MIP, the excess of H\(_2\) involved in continuous HG was found not to hamper the discharge stability,\(^ {142}\) whereas in the case of the MIP in a Beenakker resonator the excess of H\(_2\) is mostly removed by fixing the hydrides in a cold trap and releasing them at once into the MIP.\(^ {143}\) In this way, detection limits at the sub nanograms per milliliter level can be obtained (Tables 2 and 3), and also by hot-trapping in a preheated GF,\(^ {143,152,153}\) Also a Nafion\(^{a}\) membrane can be used for separating moisture or H\(_2\).\(^ {144}\) Further, one can work with microtechniques, where microaliquots are deposited on an NaBH\(_4\) pellet.\(^ {154,155}\) At well selected operating conditions, continuous HG could even be directly coupled with microwave plasmas, also for the case of real samples, such as for the determination of Se in soils.\(^ {156}\) With low-pressure microwave plasmas, the introduction of an excess of H\(_2\) was found to hamper the discharge stability less.\(^ {157}\) Also, the determination of As and Se subsequent to microwave sample dissolution and hot hydride trapping has been described.\(^ {158}\) Further, miniature hydride systems for the determination of As, Sb, Pb and Sn\(^{155}\) and the determination of Pb by HG\(^ {159}\) have been described. For their optimization, spatially

resolved studies of Ga, In, Se, Te, As and Sb lines\textsuperscript{(160)} were very useful. Not only the hydrides but also further volatile compound-forming elements can be easily determined with the aid of an MIP at a very high power of detection. This first applies to the determination of Hg with the aid of the cold vapor (CV) technique, known from AAS work. This can be done at low pressure\textsuperscript{(161)} or at atmospheric pressure\textsuperscript{(162)} and also down to ultratrace levels, as already shown in early work.\textsuperscript{(163)} By this method I also can be determined, simply by a “reverse titration”,\textsuperscript{(164)} as already shown for the case of seawater.\textsuperscript{(165)} Much work has also been done on the determination of the halogens after volatilization into an He MIP.\textsuperscript{(166)}

Cl could be determined as HCl,\textsuperscript{(167,168)} all halogens could be determined with the aid of detected ion with a surfatron MIP\textsuperscript{(169)} and also Br\textsuperscript{(170–173)} and I\textsuperscript{(174,175)} could be determined using an MIP. In the case of I, methods for differentiation between iodate and iodide in brines have been described.\textsuperscript{(176)} The influences of N\textsubscript{2} impurities on the F and Cl signals were also studied.\textsuperscript{(177)} Cl and Br could be volatilized chemically through the use of strong oxidants such as a solution of K\textsubscript{2}Cr\textsubscript{2}O\textsubscript{7} in highly concentrated sulfuric acid.\textsuperscript{(178)} Also further nonmetals can be determined by volatilization methods,\textsuperscript{(179)} including S after H\textsubscript{2}S/SO\textsubscript{2} generation.\textsuperscript{(180)} Generation of volatile species can be applied for the determination of Ni by using the formation of volatile carbonyls.\textsuperscript{(181,182)} The introduction of solid halocarbons,\textsuperscript{(183)} the determination of C, H, N and O for elemental analysis purposes with the aid of a diode-array spectrometer and atomic emission lines in the IR region\textsuperscript{(184)} and organic microanalysis have further been reported.\textsuperscript{(185)} Special attention was also given to the determination of the N species in the MIP\textsuperscript{(186)} and to the emission of H for radiation standardization purposes.\textsuperscript{(187)}

Wet aerosols are mostly generated by PN, USN or by newer techniques such as hydraulic high-pressure nebulization (HHPN). In PN with cross-flow, concentric, grid or Babington nebulizers (Figure 13a–d), the aerosol is generated by splitting off small droplets from a liquid surface by viscosity drag forces and a good description

of the relation between the gas flow nebulizing a liquid flow and the pressure decay at the nebulizer nozzle is given by the Nukuyama–Tanasawa equation. The Sauter diameter, being the diameter of the droplets for which the volume-to-surface ratio equals that of the complete aerosol, is given by Equation (22):

$$d_0 = \left( \frac{C}{\nu_G} \right) \left( \frac{\sigma}{\rho} \right)^{\frac{1}{2}} + C' \frac{\eta}{(\sigma \rho)^{\frac{1}{2}}} \left( \frac{Q_L}{Q_G} \right)^{C''}$$

where \(\nu_G\) is the gas velocity, \(Q_G\) the gas flow, \(Q_L\) the liquid flow, \(\eta\) the viscosity, \(\rho\) the density, \(\sigma\) the surface tension of the liquid, and \(C, C', C''\) and \(C'''\) are constants. When the nebulizer gas flow increases \(d_0\) becomes smaller, the sample introduction efficiency increases and so do the signals. However, as more gas is blown through the plasma, it is cooled and the residence time of the droplets decreases so that atomization, excitation and ionization also decrease. These facts counteract the increase in the signals as a result of the improved sampling. Maximum signal intensity and power of detection are thus achieved at a compromise gas flow. The size of the aerosol droplets obtained is in the low micrometer range and their diameter depends on the physical properties of the liquid as described above. Apart from PN, HHPN, as developed by Berndt and based on the expansion of a liquid jet, can also be used advantageously.

Some papers have described the use of PN subsequent to aerosol desolvation, e.g. in the case of a glass frit nebulizer and an He MIP. At moderate microwave power, desolvation even might be superfluous, as shown in the case of a Hildebrand grid nebulizer. With a Babington nebulizer it was even possible to analyze slurries directly using an MIP. Toroidal plasmas were shown to well accept wet aerosols and they are suitable for direct coupling with liquid chromatography (LC) (Figure 14a and b). In this field, refinement in HPLC and capillary zone electrophoresis (CZE) is still needed. Also, here a plasma with moderate power is advantageous. With the MPT the introduction of wet aerosols generated from aqueous and even acetonitrile-containing solutions without desolvation is possible, but with lower detection limits compared with dry aerosols (Table 4). The concomitant effects were found to be low and the system could be used for the determination of noble metals. The use of USN in MIP work was described e.g. by Michlewicz and Carnahan.

### 4.3 Sample Introduction in Medium- and High-power Microwave Plasmas

In microwave discharges operated at a power level of at least 150 W, many more techniques for sample introduction can be easily applied. This applies both to electrodeless MIPs and to single-electrode plasmas.

In the case of the MPT, it is possible to apply flow-cell HG, where the excess of the H\(_2\) produced is also led into the discharge (Figure 15). The detection limits for the volatile hydride-forming elements As, Se, etc. are in the nanograms per milliliter range and in the case of hot introduction can be easily applied. This applies both to electrodeless MIPs and to single-electrode plasmas.

In the case of the MPT, it is possible to apply flow-cell HG, where the excess of the H\(_2\) produced is also led into the discharge (Figure 15). The detection limits for the volatile hydride-forming elements As, Se, etc. are in the nanograms per milliliter range and in the case of hot trapping the absolute detection limits of Hg, As, Se and Sb are 0.1–0.2 mg. Medium-power plasmas were also found to be useful for trace determinations in gases. Also for element-specific detection in supercritical fluid chromatography (SFC), it was found that the high-power MIP can well cope with the excess of CO\(_2\) produced.
In the case of ETV the switching of gas lines for plasmas at medium and high power becomes less critical than with low-power MIPs. This has been shown for the case of the MPT, where detection limits of 3–100 pg for elements such as Ag, Au, Ge, Pb, S and Te were reported.\(^{205}\)

In the case of the CMP, the detection limits for direct volatilization of microsamples from a W cup are in the same range.\(^{206,207}\)

With PN of solutions desolvation is often still necessary, but for the MPT\(^{208}\) it becomes superfluous at powers higher than ca. 100 W.\(^{209–211}\) This allows the use of direct injection nebulization (DIN)\(^{212}\) and of flow injection analysis (FIA)\(^{213}\) also for on-line preconcentration.\(^{214}\)

USN, because of the small droplet size, is very suitable, even for the determination of nonmetals such as S\(^{215}\) and C, S and P at powers above 1 kW.\(^{216}\) Inexpensive air humidifiers can also be used for this purpose.\(^{217}\) Even for the determination of F in solutions an He MIP was found suitable.\(^{218}\) The high-power plasma torch (Figure 8) in a rectangular cavity operated with air was found to allow

the direct introduction of wet aerosols, but with a lower power of detection and higher concomitant effects than the ICP.\(^{167}\)

### 4.4 Element-specific Detection in Chromatography

Microwave plasmas, owing to their compactness and the low operating costs of the plasma source and also owing to the possibility of constructing generators with lower costs than ICP generators, are valuable sources for element-specific detection in chromatography. This applies both when they are used as radiation sources for AES and as ion sources for elemental MS. A further advance lies in the dimensions of these sources, which are very small (some a few cubic millimeters) compared with ICPs (in the cubic centimeter range). The latter is advantageous both for preserving the obtained chromatographic resolution and for realizing a high absolute power of detection.

The features of MIPs both for LC and GC were outlined in reviews such as that by Jia et al.\(^{219}\) and for the He plasmas especially that by Long et al.\(^{220}\) In GC, He is often used as the working gas, which then is very suitable for entry into microwave plasmas as they also can be operated in He and then allow the detection of nonmetals including the halogens with a high absolute power of detection. The latter is due to the possible formation of \(\text{He}_2^{+}\text{H}^+\), having energies of 18.8–21.6 eV.\(^{221}\) In the case of LC, nebulization of the effluent from the chromatographic system has to be applied before excitation with microwave plasmas is possible. This is complicated by the fact that wet aerosols, at the present state-of-the-art, cannot be entered in small microwave plasma sources without significantly influencing their stability and excitation conditions. Here research efforts have to be made, either by the design of suitable nebulization systems, working with minimal effluent flows, as is now possible with CZE, or by using alternative microwave sources still to be developed. For SFC, which is becoming of increasing interest for the detection of metal chelates,\(^{222,223}\) tolerance against the introduction of \(\text{CO}_2\) must be ensured.

The possibilities of using MIPs for element-specific detection in GC have been described in several reviews\(^{224–227}\) and their features as compared with AAS and MS have been outlined.\(^{228}\) Many papers have described the use of microwave plasmas operated at reduced pressure for element-specific GC detection [see e.g. Hobbs\(^{229}\)]. The commercially available microwave plasma detector (MPD) at reduced pressure in combination with a conventional polychromator was very useful. More recently, the MIP according to Beenakker was also used at reduced pressure for C, H and S detection.\(^{220}\) However, the breakthrough first occurred with the availability of low-power microwave plasmas at atmospheric pressure coupled with GC\(^{231}\) and of commercial equipment combining a gas chromatograph through a heated transfer line with an MIP and a suitable diode-array spectrophotometer, such as available from Hewlett-Packard (Figure 16).\(^{233,234}\) Herewith, a system using an MIP for element-specific detection also of organometallic compounds at the trace level after GC is available.\(^{235–237}\) However, this system makes use of a plasma as described by Beenakker, which is not the only possible way, as shown by work using a surfatron MIP\(^{238}\) with the same spectrometer or by systems constructed from different components.\(^{239}\) Here both glass capillaries\(^{240}\) and fused-silica capillaries\(^{45}\) can be used.

Comparisons were made between MIPs operated with He only and those operated with He–Ar mixtures.\(^{241}\) With respect to the types of MIPs used, the surfatron,\(^{242}\) the MIP according to Beenakker and other types were compared.\(^{243}\) Such studies also include noise studies, as was done in the case of the surfatron\(^{244}\) and the MPT.\(^{245}\) With respect to torch design, both a tangential flow torch and a capillary water-cooled MIP torch can be used, where the latter was found to result in the best sensitivity.\(^{246}\)

**Figure 16** Re-entrant cavity for gas chromatography/microwave-induced plasma atomic emission detector (GC/MIPAED) system. (1) Pedestal; (2) quartz jacket; (3) coupling loop; (4) main cavity body; (5) cavity cover plate; (6) gasket; (7,8) cooling water inlet and outlet; (9,10) water plates; (11) O-ring; (12) silica discharge tube; (13) polyimide ferrule; (14) exit chamber; (15,16) window purge inlet and outlet; (17) spark器 wire; (18) window; (19) gas union; (20) threaded collar; (21) column; (22) capillary column fitting; (23) makeup and reagent gas inlet; (24) purge flow outlets; (25) stainless steel plate; (26) standoff; (27) heater block; (28) mounting flange; (29) brass center conductor; (30) PTFE coaxial insulator.\(^{232}\) (Reprinted with permission from B.D. Quimby, J.J. Sullivan, Anal. Chem., 62(10), 1027–1034 (1990). Copyright 1990, American Chemical Society.)
Further, different torch tube materials can be used, such as BN and quartz. The former material is brittle but is more resistant to etching by chromatographic effluents such as acetone and acetonitrile. Laminar-flow torches were found to give better results in the determination of empirical formulas than the other types, as shown in the case of dioxins and pyrethroids.\(^{247}\) Apart from the already mentioned types of MIPs, microwave plasmas generated at about 15 W\(^{248}\) between the tip of a hollow metal electrode (e.g. the GC capillary end) and an annular electrode surrounding the tip have also been used.\(^{249}\) Power modulation of the plasma at 10 Hz has also been applied and found useful to maximize the excitation efficiency of the MIP.\(^{250}\) For the detection of dioxins the use of a tangential torch, of low flow rates and of low power, was found to give the best sensitivity.\(^{251}\) It was even found possible to use the reflected power of the MIP for registration of the chromatogram.\(^{252}\) Also the VIS wavelength range often is used in the case of nonmetals.\(^{253,254}\) Here Fourier transform spectrometry is very useful and allows multiwavelength measurements.\(^{255}\) Apart from rather expensive dispersive spectrometers using a diode array, interference filtering\(^{256}\) can also be used. Attention must also be given to the acquisition of the spectral background, which may be influenced by the effluent. This can be done by using rapid scanning techniques, as has long been known.\(^{257}\) Multicapillary GC is very useful for obtaining high throughput at high resolution, as shown for hydrocarbons and organonitrogen compound separations.\(^{258}\) On-column detection is also useful in elemental ratio detection,\(^{259}\) as then the chromatographic resolution is maintained. This has been described for the characterization of an organomercury reference material held on microcolumns.\(^{260}\) Also the use of zero-dead-volume cross and PTFE transfer lines in headspace work for organomercury detection has been shown to be useful in minimizing memory effects.\(^{261}\) Further, provisions for solvent venting have to be realized in the coupling between GC and MIP, as already known from low-pressure MPD.\(^{262}\) Here heated Al tubes are used and near to the plasma one employs all-glass open-split connections\(^{263}\) and zero-transfer line systems.\(^{264}\) The He MIP can even be operated as a very soft electron source and used as an alternative to a \(\beta\)-emitter in electron-capture detection.\(^{265}\)

Many papers have dealt with the optimization and use of the gas chromatography/atomic emission detector (GC/AED) system for element-specific detection. It has been increasingly used for speciation in environmental samples for both metals and nonmetals [for a state-of-the-art report, see e.g. Lobinski and Adams.\(^{266}\) During optimization special attention has to be paid to memory effects arising from deposits and also from the detector response, which could become of relevance in high-speed GC.\(^{267}\) For the optimization factorial analysis was applied and response surfaces were studied.\(^{268}\) Influences of the compound structures on the elemental response obtained were also investigated.\(^{269}\) Further, noise studies were performed and showed some flicker noise contributions of the plasma depending on the concentration range of the analytes.\(^{270}\) Detection with a microwave-induced plasma/atomic emission detector (MIP/AED) was found to facilitate considerably the structure of gas chromatograms as compared with those obtained with conventional detection, as shown for polychlorinated biphenyl (PCB) mixtures and also for amines\(^{271}\) and carboxylic acids\(^{272}\) both after derivatization. As one works with an He plasma nonmetals can be detected with low detection limits.\(^{273}\)

In view of the possibility of elemental analysis of organic compounds, efforts were made to determine O selectively. This was found to be difficult because of the need to exclude contributions from the atmosphere. This necessitates purification of the scavenger and carrier gas but also optimization of the viewing position in the plasma.\(^{277}\) of the gas flow rates\(^{278}\) and of the addition of Cu as catalyst and of I\(_2\) to reduce the spectral background for O.\(^{279}\) Also the detection of H was optimized.\(^{280}\) As the signals of deuterated and nondeuterated compounds can often be separated by GC/AED this is of interest for the control of deuteration experiments. This can be performed both in solution and in the gas phase with suitable provisions,\(^{281}\) but unfortunately the spectral lines of \(^1\)H and \(^2\)H partially overlap.\(^{282}\) The method was shown to be suitable in the separation of the deuteroisotopomers of caffeine.\(^{283}\) The detection of C has also been carefully studied. After optimization \(^13\)C can be detected down to the sub-picograms per second level.\(^{284}\) Owing to the experience with the detection of C and H, alkanes could be unambiguously identified in gas chromatograms, based on the C/H ratios\(^{285}\) and empirical formula determinations can also be performed.\(^{286}\) This has been shown, for example, for polymer pyrolyzates.\(^{287,288}\) As N can also be well determined,\(^{289}\) the GC/AED system could be applied to a wide diversity of organics.

The halogens certainly can be detected with an He MIP, as shown with a system using an oscillating filter-based detection system, developed by Mueller and Cammann.\(^{290}\) Accordingly, empirical formulas can also be determined for chlorinated hydrocarbons\(^{291}\) even including the fluorinated compounds\(^{292,293}\) and quantitative determinations of dioxins and dibenzofurans were shown to be possible in the micrograms per milliliter range.\(^{294}\) The results agreed with those of MS detection and also in the case of determinations of chlorophenols.\(^{295}\) However, it was shown.
that the structure of the halogenated compounds can influence the elemental signals obtained. Further, brominated compounds can also be detected, as shown for hydrocarbons or after derivatization with phenylboronic acid. For S the power of detection of the MIP was shown to be better than that with chemiluminescence detection. With the S 525.45-nm line a high power of detection and linearity were reported. The element-specific detection of B was shown to permit the determination of organoboron compounds in motor and lubricating oils by GC/AED. Detection of Si down to a few picograms as required for the determination of organosilicon compounds was shown to necessitate the use of plasma discharge tubes made of BN or alumina.

Organoarsenicals can also be determined by GC/AED. This could be shown for the determination of the methylated arsines together with organomercurials in oil shale and for the analysis of complex organoarsenical mixtures, also after derivatization. Further interesting applications of GC/AED analysis are in the analysis of petroleum-related products for dioxane, the analysis of gasoline for oxygenated compounds, the determination of the halogenated products of hemic substances in water, pesticide residue analysis and dioxin detection. The use of a GC/MIPAED for the determination of molecular impurities such as CH₄ in Ar or for the determination of organomercury compounds in air, after trapping them on Chromosorb, has been described.

Apart from nonmetals, metal chelates can also be determined with GC/MIPAED and its application to metal speciation has been widely studied. The latter field especially developed through coupling of chromatography and atomic spectroscopy (for a review see Lobinski). Such work was initiated in 1980 and has now been performed for Fe, Ge, Hg, Ni, Pb, Se, Sn and V species, as discussed by Lobinski and Adams. Organotin determinations in water samples and sediments were performed, including a thorough optimization of the sample preparation and the measurement conditions. Also a derivatization by a Grignard reaction often is applied [see e.g. Tutschku et al.]. The determination of alkyllead compounds was described very early. A review on the optimization of microwave-induced plasma/gas chromatography (MIP/GC) determinations of organolead and organomercury compounds with the aid of simplex methods was given by Greenway and Barnett. For the speciation of Hg, however, cold vapor atomic absorption spectroscopy (CVAAS) and AFS are very powerful. The determination of methylmercury in biological samples has been performed with headspace techniques. After derivatization, methylmercury could be determined in fish subsequent to microwave-assisted extraction. In addition to speciation, pre-enrichment for inorganic analysis can also be performed as shown by the preconcentration of Be from natural waters with the aid of acetylacetones. The use of acetylacetones could also be applied in the determination of Ni and Cu in ores. Further fluorinated and non-fluorinated tetradentate β-ketoaminate ligands could be used in the determination of Pd. Se(V) could be determined by volatilization after ethylation with tetraethylborate and volatile Ni, V and Fe porphyrins could be determined directly in crude oils.

Also for element-specific detection in LC, carefully optimized types of MIPs already have some prospects. This is certainly true when using desolvated aerosols, as shown by Billiet et al. The latter especially makes sense with USN, after which halides and oxyhalide salts subsequent to anion exchange could be determined. Further, dry aerosol generation with a moving-wheel system is also possible.

PN without desolvation also could be shown to be of use. Kollotzek et al. used a toroidal mixed-gas MIP in a Beenakker cavity to obtain element-specific signals for Hg. Also the modified MPT can take up wet aerosols without applying desolvation. This is even possible for acetonitrile-containing solutions, but with deterioration in the power of detection, as shown e.g. also for Cr. The case of Hg the problems can be solved by an on-line CV technique between the exit of the HPLC system and the MIP. However, care must be taken to minimize dead volumes so as not to deteriorate the chromatographic resolution. Wet aerosols produced with a frit nebulizer in the case of microcolumn HPLC with some restrictions can be led into MIPs. In CZE work the effluent rates are low. When using an ion-exchange membrane as an electrical junction in front of the capillary, dead volumes can be minimized and with high-efficiency nebulizers sensitive detection becomes possible. Also for element-specific detection in ion chromatography the use of MIPOES has been described.

For element-specific detection in SFC, the gases used are very important. Mostly CO₂ is used and it was shown that in the case of an He MIP a sensitive detection of S, Cl and P is possible. The use of Xe both for atmospheric- and low-pressure plasma sources cannot be justified. Also the use of N₂O as mobile phase was reported to allow the sensitive detection of Cl, Br, I, S and P considerably. Binary mobile phases such as CO₂ with methanol addition also have prospects especially for the extraction of metal chelates and these mixed phases were shown to be tolerated by the MIP. Further, the use of medium-power MIPs was shown to be advantageous so as to reduce the influence of the mobile phase of the stability.
of the MIP.\textsuperscript{(342)} Jin et al. showed that the MPT was very useful in the case of SFC and in OES they reported a detection limit for Cl of 300 pg.\textsuperscript{(343)} A surfatron can also be used for element-specific detection in SFC for the determination of S-containing aromatics.\textsuperscript{(344)} The NIR lines can also be used, as shown for the detection of S and Cl.\textsuperscript{(345)} With CO$_2$ as mobile phase and an He MIP, Zhang et al. reported a detection limit for Cl of 40 pg s$^{-1}$\textsuperscript{.}\textsuperscript{(346)} Webster and Carnahan also proposed the use of internal standards to cope with the influence of the effluent gases on the plasma in the case of nonmetal detection.\textsuperscript{(347)} With the example of ferrocene, it could be shown that the approach is also viable for the isolation and determination of organometallics.\textsuperscript{(348)} In the case of packed columns, the detection limit of supercritical fluid chromatography/microwave-induced plasma (SFC/MIP) detection of Fe was reported to be 30 pg.\textsuperscript{(349)}

4.5 Glow Discharges

Since the work of Paschen on hollow cathodes,\textsuperscript{(350)} the GD has become well known as a source for atomic spectroscopic analyses, especially in the case of solid samples. GDs are operated at low pressure. In a classical GD there are different zones, where the formation of excited species takes place. Near the cathode positive ions are accelerated and impact on the cathode practically without any energy exchange with gas ions (dark zone), whereas in the negative glow the free electron concentrations are high and considerable ionization of the gas takes place. Near the anode the energy conversion is again very low. Accordingly, volatilization, excitation and ionization processes differ widely from those in plasma sources operated at atmospheric pressure. As outlined in state-of-the-art reviews,\textsuperscript{(351,352)} the samples to be analyzed mostly constitute or are placed in one of the electrodes, preferably the cathode. From here they can be volatilized by cathodic sputtering resulting from the impact of heavy gas ions formed in the negative glow of the discharge. Often heating of the cathode also occurs and this still enhances sample volatilization and in some cases it is the process mainly responsible for material volatilization. Excitation and ionization mainly result from electron impact; however, collisions with metastables, which have a long lifetime in a discharge at reduced pressure, and charge transfer\textsuperscript{(353)} may also play a role. GDs may be produced by dc and also with rf energy, as proposed for the spectrochemical analysis especially of non-conducting samples by Winchester et al.\textsuperscript{(354)} and other groups. Indeed, as the electrons can take up energy in the high-frequency field much better than the heavy positive ions do, a bias potential is built up in front of the sample, through which the field is coupled into the working gas. Accordingly, sputtering through the presence of this field can occur as in a dc field, but also for electrically nonconducting samples. Although GDs are now routinely used for solids analysis, especially when it comes to depth profiling as is now required for new surface-improved materials (for a thorough review see Bengtson\textsuperscript{(355)}, its potential is not fully used. Indeed, much of the sputtered material is not excited and certainly not ionized in the optically thin low-pressure discharge. Therefore, already in early work endeavors to achieve cross-excitation were made. Leis et al.\textsuperscript{(356)} successfully designed a GD incorporating cross-excitation of the sputtered material in an MIP produced at low pressure in a resonator according to Beenakker, which is constructed just in front of the GD source (Figure 17). The system was optimized and it could be shown that owing to the increased excitation efficiencies the line intensities in OES were considerably improved, but also the spectral background intensities. It could be shown by Fourier transform high-resolution studies of line profiles\textsuperscript{(357,358)} that the self-reversal in the case of microwave boosting diminishes. This proves the increase in the excitation and ionization efficiency in the plasma especially in front of the sample. For steels a gain in power of detection by up to an order of magnitude could be realized (Table 5) and the system also could be used successfully for the analysis of Al, Cu and Pb samples.\textsuperscript{(359)} Similar results were also reported by other groups.\textsuperscript{(360)} The analyte signal enhancements due to microwave boosting seemed to be at least as strong for a microsecond-pulsed GD.\textsuperscript{(361)}

Hollow cathodes have also been widely applied as atomic emission spectrochemical sources. Here the

The analyte residence time in the plasma is very high, leading to high excitation and ionization efficiencies. Also here microwave boosting was found to increase the excitation and ionization efficiencies and accordingly the analytical signals. These sources have been found especially useful for dry solution residue analysis; however, they also might have potential for elemental detection in GC, because of the low gas consumption and simple power supply systems.

5 OPTICAL ATOMIC SPECTROSCOPY WITH MICROWAVE PLASMAS

Many method developments in optical atomic spectrochemical procedures making use of MIPs have been described. For this purpose conventional grating spectrometers using gratings with constants down to 1/3600 mm and focal lengths of 0.5–1 m with a Czerny–Turner or Ebert set-up are used and sequential systems or simultaneous spectrometers including polychromators mainly use a Paschen–Runge mounting (Figure 18a–d). Radiation measurements are made with photomultipliers but also more and more with diode-array detection, as then line and background intensities for the atomic spectral lines can be recorded simultaneously. The latter systems also are very useful for measurements of band intensities, as shown in the case of the OH bands (Figure 19a and b), which are required for the determination of rotational temperatures. Here illumination of the entrance slit with a 90° rotated image of the plasma and measurements at different heights along each rotational line allow tomography of the plasma for the rotational temperature, as shown as an example in Figure 20.

Figure 18 Optical mountings for optical spectrometers with a plane grating. (a) Ebert; (b) Czerny–Turner; (c) Seya–Na-mioka; (d) Paschen–Runge. S_e = Entrance slit; S_a = exit slit; g_p = plane grating; g_c = concave grating; m = mirror.
Figure 19 OH band at 306.4 nm. (a) CCD image; (b) signal of one row of the CCD image.\(^{96}\)

Figure 20 Radially resolved rotational temperatures in an Ar MPT (forward power 100 W, 150 mL min\(^{-1}\) working gas, 450 mL min\(^{-1}\) carrier gas).\(^{96}\)

More advanced spectrometers can also be used, such as those including an interferometer and a photodiode-array detector\(^{364}\) or a Fourier transform spectrometer (for a tutorial discussion, see Faires\(^{365}\)).

Figure 21 Échelle spectrometer with crossed dispersion and charge injection device (CID) detector for plasma spectrometry (courtesy of Perkin-Elmer Corporation).

Particularly interesting also is the use of échelle spectrometers with crossed dispersion (see Figure 21). Here an échelle grating with a small number of lines (often down to 50 lines mm\(^{-1}\)), a high order (30 and more) and a prism is employed, which has its dispersion direction perpendicular to that of the grating so as to separate the different spectral orders. Accordingly, a two-dimensional spectrum is obtained. As échelle systems require the use of a small slit height, high radiation density sources are required so as not to come into shot-noise limitations with the detector. As microwave plasmas also at low power fulfill this condition, they easily can be used together with échelle spectrometers realizing both high resolution with short focal length spectrometers, absence from shot-noise limitations and high resolving power. This combination is particularly promising as two-dimensional array detectors then also allow simultaneous multielement detection with true background correction.

Systems with N\(_2\)-purged optics have also been used, with which the lines at vacuum-ultraviolet (VUV) wavelengths for I become accessible.\(^{366}\) Method development depends, of course, on the type of microwave plasma used in particular and it will be outlined for the low- and medium-power MIPs, the single-electrode plasmas and the related stabilized capacitively coupled high-frequency plasma (SCP), as well as for atomic emission, absorption, fluorescence and laser-induced ionization.

5.1 Atomic Emission Spectroscopy with Low-power Microwave-induced Plasmas

The special features of the low-power MIPs are their low instrument and operating costs, but they are restricted in their use to those techniques where gaseous and dry analyte clouds are entered into the plasma. This has been discussed for ETV and HG and also includes the use of
volatile compound formation, as developed, for instance, for the determination of I.\textsuperscript{367} Here detection limits below 100 \textit{ng mL}\textsuperscript{-1} can easily be obtained. The determination of Hg can also be performed with extremely low detection limits, as here the small volume of the source, the absence of an excess of H\textsubscript{2} when reducing with SnCl\textsubscript{2} and the possibility of using He are very favorable conditions. Here the use of a surfatron source was shown to allow the highest sensitivity.\textsuperscript{368} For the determination of N in natural gas, a low-pressure microwave plasma was found to permit detection limits down to 0.01 ppm by using the band heads at 336 and 337 nm\textsuperscript{369} and also O could be determined from the OH band emission.\textsuperscript{370} For the low-power microwave plasma sources dopants were found to considerably influence the atomic line intensities, as shown for the case of Sn analyte lines in the GC of alkylated Sn compounds.\textsuperscript{371} Low-power microwave plasmas in the case of Ar as working gas further seemed particularly useful for the excitation of elements with low excitation potentials such as alkali metals.\textsuperscript{372}

### 5.2 Single-electrode Microwave Plasmas

Single-electrode CMPs are very stable in the case of many techniques for sample introduction. They can be operated between about 200 and 600 W with different gases. It might be problematic, however, to enter the analytes in an efficient way into the hot plasma center. For this purpose the aerosols are often led into the CMP through holes near the plasma tip and wall stabilization with the aid of a mantle gas flow is used, as described by Patel et al.\textsuperscript{373} In the case of a high-power plasma a graphite cup which contains the sample can even be an integrated part of the torch.\textsuperscript{374} At a sufficiently high power the CMP can easily be operated with air only and, as shown by Bings et al.,\textsuperscript{32} the excitation and rotational temperatures in this source are still in the 5000 and 4000 K range, respectively. As shown already for many elements by Zhang et al.,\textsuperscript{375} the detection limits in aqueous solutions with this source are still in the sub-micrograms per liter range. A CMP can be operated also in He/H\textsubscript{2} at the tip of a graphite electrode\textsuperscript{376} with a power of up to 800 W. The addition of H\textsubscript{2} was found to remove typical volatilization interferences such as the Ca\textsuperscript{2+}–PO\textsubscript{4}\textsuperscript{3−} interference. With an He CMP Cl and Br can also be determined down to detection limits of 1 and 0.4 \textit{µg mL}\textsuperscript{-1}, respectively, as required in the case of organohalogenated compounds.\textsuperscript{377} With ETV Si can be determined with a detection limit as low as 0.03 \textit{µg mL}\textsuperscript{-1} and in the case of PN 0.3 \textit{µg mL}\textsuperscript{-1}.\textsuperscript{378} With an He CMP organotin compounds can determined in GC effluents with a detection limit of 1 \textit{ng}.\textsuperscript{379}

When combining OES using the CMP with HG, As can be determined with absolute detection limits of down to 60 pg in the case of CT.\textsuperscript{380} In GC, element-specific detection of the halogens can be performed\textsuperscript{381,382} H and O can be determined in metals by heating the samples and bringing the released gases into the CMP.\textsuperscript{383} The plasma even is so stable that insertion of samples in microcups placed on the tip of the electrode is possible. Then extremely low absolute detection limits are obtained, e.g. 8 pg in the case of Cd.\textsuperscript{384,385} From an external GF several heavy metals in National Institute of Science and Technology (NIST) fly ash and tomato leaf samples could be evaporated and determined with the CMP.\textsuperscript{386} For Hg, thermal vaporization with steam led to a detection limit of 1 \textit{µg L}\textsuperscript{-1} with the CMP.\textsuperscript{387} In the case of wet aerosols desolvation can be applied and just as in ICPOES it may improve the detection limits.\textsuperscript{388} However, wet aerosols can easily be entered directly into the plasma, especially when using a tubular electrode of Ta or Al.\textsuperscript{33,389} The plasma can also take up solvent-loaded aerosols obtained by the PN of organic solutions, which made it possible to use the CMP to perform analysis in oils eventually after dilution with the appropriate organic solvent\textsuperscript{390} (Table 6).

As in the plasma the ground-state atom population is still considerable, the CMP can also be used as an atom reservoir for atomic absorption work.\textsuperscript{34}

### 5.3 Plasma Torch Sources

In a review, Blades\textsuperscript{391} showed the state of development of He MPTs and other microwave plasmas and compared them with the ICP. The so-called microwave-induced nitrogen discharge at atmospheric pressure (MINDAP) source described by Deutsch et al.\textsuperscript{392,393} operates at high power and it is shown that also in a Beenakker cavity an

N₂ discharge can accept wet aerosols with low detection limits, especially for the alkali metals. The MPT, however, became a well-studied source. A comparison with the surfatron showed that for Hg determinations the two sources have similar performances. However, in the case of H₂ produced in chemical HG together with the hydrides into the plasma, which also was found to be possible with a TE₀₁₀ cavity MIP in the case of electrochemical HG. In the case of the MPT, volatilization also was used for the determination of the halogens in aqueous solutions. For the nonmetals also the sensitive lines in the IR region are accessible with Fourier transform spectroscopy, as shown for a high-power MIP. Flow injection can be coupled on-line with OES using an MPT in the case of USN including desolvation or of PN and desolvation and Cd, Cu, Mn and Zn can be determined at concentrations down to some nanograms per milliliter. The necessity for desolvation, however, is not always given. This could be confirmed by measurements with a Légère nebulizer, where desolvation proved to be not necessary at all. Also, ion exchange can be very efficiently coupled on-line with an MPT, as shown by the determination of B using cation exchange and also for metals forming chloro complexes in the case of anion exchange. Ion exchange could be applied for a removal of the matrix element Fe in the determination of Si in steel. The analytical performance of the MPT was also demonstrated by the determination of the rare earths in solutions using USN. It was shown that with He as discharge gas, the halogens, P and S could be determined at the 100 ng mL⁻¹ level. At high power (>500 W), it was shown by Urh and Carnahan that MPT discharges can take up wet aerosols without any problem. Then also Cl could be determined with an ICP like torch positioned in a rectangular resonator. Leis and Broekaert showed that with wet aerosols sub-µg mL⁻¹ detection limits can be obtained but that the interferences by easily ionized elements are less favorable than in ICPOES.

5.4 Stabilized Capacitively Coupled Plasma

The SCP described by Gross et al. through its low operating power, is very similar in its features to low-power microwave plasmas. It is operated between two ring-shaped electrodes at 200 W and has a diameter of 1 mm, defined by the water-cooled plasma capillary (Figure 22). Originally designed for element-specific detection in GC, it can also be well used for the detection of nonmetals after volatilization and in combination with all dry vapor generation devices, including HG without removal of the H₂, ETV and PN using desolvation.

As the ground-state atom population densities in the case of microwave plasma discharges are still high and the plasma volumes small, microwave discharges in a number of cases could be very well used as atom reservoirs. This was shown for the case of the MPT in which samples were introduced by USN. Here with AAS lower detection limits could be obtained than in the case of the MIP. For sample introduction GF evaporation could also be combined with the MPT and in the case of a Beenaeker MIP PN with a glass frit nebulizer also was applied for AAS measurements. The performance in the case of desolvation is improved as also for an MPT as described by Duan et al. Because of the longer pathlength and decreases in matrix effects in the latter case, axial measurements are worth considering.

Apart from hollow-cathode lamps, diode lasers can also be used as primary radiation sources for AAS. For the halogens a low-pressure He MIP can be used as atom reservoir, thus allowing the detection of Cl compounds through the metastable Cl levels in GC effluents. Applications of microwave plasma torch atomic absorption spectrometry (MPT AAS) include the determination of Cd.

For atomic fluorescence both line (hollow-cathode lamps) and continuous sources (Xe arc) were applied
in the case of a high-power Ar MIP according to Beenakker,\textsuperscript{421} but the detection limits obtained were poorer than those in AAS and OES. In the case of an He MIP nonmetals could also be determined\textsuperscript{423} and detection limits of 0.25 ng mL\textsuperscript{-1} Cd and 120 ng mL\textsuperscript{-1} As can be obtained with AFS\textsuperscript{423} and 3 ng mL\textsuperscript{-1} for Hg.\textsuperscript{424} For the determination of down to 10 µg L\textsuperscript{-1} Na, ETV from a W filament and AFS in an MIP could be successfully applied.\textsuperscript{425} For the determination of Fe, Ni and Co in pure water, introduction of their volatile carbonyls could be applied.\textsuperscript{426} The full power of detection of AFS for the analysis of pure waters can only be obtained with laser excitation; only then can saturation of the excited levels be obtained, as shown in work using ETV from a W filament and an MIP.\textsuperscript{427} LEI (laser-enhanced ionization) can also be performed with an MIP as atom reservoir. Here the ion currents resulting from increases in ionization when populating the excited states of analytes with the aid of laser radiation of a suitable wavelength are measured and the technique is well known from flame work.\textsuperscript{428} As the method needs no spectrometric equipment at all (Figure 23), its instrumentation costs are low but nevertheless the method is very sensitive and even isotope-selective determinations are possible. The features of a set-up using a nitrogen MIP and an Ar ion laser were shown in the case of Na, for which a detection limit of a few nanograms per milliliter was obtained.\textsuperscript{429} Especially, the electrical characteristics of the plasma and their effect on ion detection have to be studied.\textsuperscript{430} With a microarc atomizer and LEI in a nitrogen plasma using a flashlamp-pumped dye laser, In could be determined down to the picogram level.\textsuperscript{431}

Comparative studies of AAS, AFS and OES with an MIP for the case of Hg revealed differences in detection limits of less than a factor of two.\textsuperscript{432} The plasma afterglow can also be used for atomization.\textsuperscript{433}

6 MASS SPECTROMETRY WITH MICROWAVE PLASMAS

Also for plasma MS, MIPs have been used as ion source.\textsuperscript{434,435} They even were used earlier than the ICP. The latter became more successful, as with aqueous solution analysis desolvation was not required. However, MIPs in their whole variety at low and high power and at atmospheric and reduced pressure, just as the ICP, are of use as ion sources for MS. This could be shown for the detection of metals and nonmetals in aqueous solutions.\textsuperscript{436} Microwave-induced plasma mass spectrometry (MIPMS) especially found use for element-specific detection in chromatography.\textsuperscript{437–440} Compared with OES, MS not only has the advantage of increased power of detection but it also permits the determination of isotope ratios, with a precision of better than 3\% in the case of comparable abundances.\textsuperscript{441}

6.1 Low-power Microwave Plasmas

Especially at low pressure and in the case of He as discharge gas, MIPs have been shown to be very useful ionization sources for MS and both dry vapors and as solvent-loaded aerosols\textsuperscript{442} and organics\textsuperscript{443} can be introduced. These working conditions especially promote microwave discharges to soft ionization sources, yielding molecular and radical species, as does electron impact ionization. Their use facilitates the identification of chromatographic peaks\textsuperscript{444} and in this respect MIPs have similar potential to low-pressure rf plasmas.\textsuperscript{445}

At atmospheric pressure the use of a nitrogen MIP and USN including desolvation has been described. In this case, however, contributions of N species to the background were found to be considerable.\textsuperscript{446} With a high-power MIP operated in a surfatron, desolvation even in the case of USN was found not to be necessary.\textsuperscript{447} Particularly with low-power MIPs in a TM\textsubscript{010} cavity, fragmentation spectra could be obtained, when working under reduced pressure and at the lowest possible power.\textsuperscript{448} Especially in the case of He the MPT also became of use as ion source for MS. When operated at 150 W and using USN and subsequent desolvation, the nonmetals could be determined with detection limits below 1 µg mL\textsuperscript{-1}.\textsuperscript{449} Especially for GC detection, MIP/MS became recognized as very powerful.\textsuperscript{450} This is due to the small
MICROWAVE-INDUCED PLASMA SYSTEMS IN ATOMIC SPECTROSCOPY

Figure 24 TOF (time-of-flight mass spectrum of CCl4 obtained with the MPT and a flow cell sample introduction technique with the use of a digital oscilloscope for data acquisition. Peaks arising from air entrainment have been eliminated by a flowing sheath of N2. Peak undershoot is caused by the high-speed amplifier used in this study.\(^{453}\)

volume of the MIP, which keeps the deterioration of the high resolution in GC work to the minimum. The He MPT became of use for the detection of many elements by GC, including the halogens,\(^{451}\) O and H.\(^{452}\) For this application microwave plasma torch time-of-flight mass spectrometry (MPTTOFMS) is very useful. Here the chromatographic speed and resolution can remain high while acquiring all element and radical signals for a peak simultaneously. Accordingly, complete mass spectra, except for the range around the He ion and the N species stemming from the surrounding atmosphere and which cannot be completely removed by deflection (Figure 24), can be recorded. As the mass spectrometer ion conductance remains high compared with quadrupoles, one can achieve very low absolute detection limits, as found with halogenated hydrocarbons (see Table 7). Elemental ratio determinations and isotopic dilution in principle can also be performed with high precision compared with sequentially operating quadrupoles and sector field instruments.

Many studies have been devoted to the detection of the halogens, because of the environmental interest in the detection of halogenated hydrocarbons. The detection of Br, Cl and I down to the picogram level is possible with a low-pressure MIP in a resonator according to Beenakker\(^{455}\) when working in the positive ion mode.\(^{456}\) This value is still lower in the case of MPTTOFMS as discussed.\(^{453}\) The detection of P and S, which is especially interesting from the point of view of pesticide residue analysis, could be performed with a water-cooled low-pressure MIP.\(^{457}\) The atmospheric pressure plasma in this case was found to give more background species.\(^{458}\) For such applications a tangential flow torch was often found advantageous.\(^{454}\) The mass spectra for organics in the case of plasmas in O\(_2\) or N\(_2\) were also studied\(^{459}\) and clusters identified.\(^{460}\) The system can accordingly be very useful for elemental analysis.\(^{454}\) However, organometallics can also be well determined, as impressively shown for the case of the alkylated Sn compounds.\(^{461}\)

GC often has the disadvantage of requiring derivatization of the analytes so as to obtain volatile compounds. This is not necessary when applying SFC. In the case of halogenated compounds this could be well applied in combination with element-specific detection by MIPMS when using CO\(_2\) and a low-power plasma.\(^{462}\) HPLC could be applied for the case of halogenated compounds and also organoarsenicals, but requires the use of a 300 W MIP.\(^{463}\)

Apart from its use in combination with chromatography, MIPMS in the case of vapor generation can also be applied for the determination of nonmetals. Here Cl, Br, I and S compounds\(^{464,465}\) can be determined down to the nanograms per milliliter level. Se in water can also

be determined after its volatilization as a complex into MIPMS\(^{466}\) and halogens and Br-containing species after volatilizing their derivatives.\(^{467}\)

### 6.2 High-power Microwave Plasmas

The introduction of high-power microwave plasmas as ion sources for MS is aimed at the use of conventional nebulization of solutions without need for desolvation. This is possible at 150 W when using a micronebulizer; for Pd, Ru and Rh detection limits down to 0.04 \(\mu\)g mL\(^{-1}\) could be achieved in this way with AES\(^{468}\) and with an He MIP at 350 W detection limits for Se and Cd of 19 and 0.9 ng mL\(^{-1}\), respectively, could be obtained with MIPMS. when applying direct solution analysis using DIN.\(^{469}\) At a moderate power of 500 W, an \(\text{N}_2\)-operated MIP can easily accept nondesolvated aerosols. When using a water-cooled torch\(^{470}\) or an \(\text{Al}_2\text{O}_3\) tube,\(^{471}\) the detection limits for Ca and K were shown to be lower than those with the ICP. The use of an annular nitrogen microwave plasma at 1.3 kW removes all restrictions for solution work and in MS detection limits down to the picograms per milliliter level have been reported.\(^{472}\) The source was used for the analysis of biological samples using calibration by isotopic dilution\(^{473}\) and even work with high salt concentrations was found to be possible.\(^{474}\) The source also can easily cope with organics when using \(\text{O}_2\) as the working gas, as shown in the analysis of photoresists.\(^{475}\)

### 7 APPLICATIONS OF MICROWAVE PLASMA ATOMIC SPECTROSCOPY

The applications of microwave plasma atomic spectroscopy narrowly hang together with the types of available instrumentaton. Therefore, element-specific detection in GC for residue analysis and now also for metal speciation is a major field of study. A review dealing with topics from the coupling of AAS to GC to the use of the MIP illustrates this development\(^{476}\) and the importance of coupled techniques for speciation in general is now obvious.\(^{477}\) As shown e.g. by the determination of organomercurials in biological materials,\(^{478}\) the coupling of the MIP to GC is now well developed. There are, however, precautions to be taken in calibrating for organometallic compounds as a result of their stability [for organomercury compounds, see e.g. Lansens et al.\(^{479}\)] and there is certainly room for advanced spectroscopic concepts\(^{480}\) making the system cheaper.

#### 7.1 Analysis of Biological Samples

As shown in a review,\(^{481}\) most MIP work for the analysis of biological samples makes use of volatile compound formation using hydrides or GC subsequent to derivatization [see Krull et al.\(^{482}\),\(^{483}\)] or ETV. For biological studies \(^{15}\)N detection is very important, as discussed by Deruaz et al.\(^{484}\) and makes thorough optimization of column separation and MIP detection necessary.

With respect to plants, volatile elements have been determined in tobacco using sampling of fumes on Tenax\(^{\oplus}\) tubes and thermal desorption with subsequent gas chromatography/mass spectrometry (GC/MS) or GC/AED.\(^{485}\) Pesticide residue analyses\(^{486}\) e.g. in the case of fruit,\(^{487}\) also are of crucial importance and may make use of Cl-specific MIP detection. Further, the volatile hydride-forming elements As, Sb and Se have been determined in Chinese tea, and electrochemical HG was found to give detection limits as low as the chemical conventional method using NaBH\(_4\).\(^{395}\) In the case of the speciation of Se, GC has to be included, as shown for the determination of selenomethionine in wheat.\(^{488}\) The power of detection of these procedures is well illustrated by the analysis of human garlic breath for organoselenium compounds.\(^{489}\) Also in beer, S compounds and coffee can be determined with gas chromatography/microwave-induced plasma optical emission spectrometry (GC/MIP-OES) subsequent to suitable trapping.\(^{490}\) With respect to organometallic species, especially the determination of organolead in wine has been studied\(^{491}\) and for very volatile species such as the organomercurials headspace techniques were optimized.\(^{492}\) ETV from a GF, as already shown by Aziz\(^{119}\) (Figure 25), can be very well combined even with a low-power MIP and used for determinations in plant materials. This also applies to the direct determination of very volatile elements in solids such as As\(^{493}\) in leaves and for Pd, Cd. With selective volatilization speciation also can be realized, as shown for Hg and As compounds.\(^{494}\)

In blood\(^{495}\) and in water and urine,\(^{496}\) F-containing compounds could be determined with GC coupled to MIPOES. As metals, and especially total Hg concentrations\(^{497}\) and organomercurials,\(^{498}\) and also Pb have been determined. For the determination of Pb in blood, the CMP could be used very successfully when applying dry residue analysis in a W cup placed on top of the electrode.\(^{499}-501\) In fish tissue especially organomercury compounds have to be determined\(^{502},503\) and also the element Se [see e.g. Tsunoda et al.\(^{504}\)]. As has been determined in human air, pig kidney and mussel tissue by electrochemical HG combined with hot trapping and CT.\(^{505}\) For the determination of organotin compounds in tissue, microwave-assisted leaching procedures have been shown to be very helpful,\(^{506}\) but clean-up of the extracts and derivatization of the organotin compounds are required.\(^{507}\)
7.2 Analysis of Environmental Samples

MIPs have been used both for the determination of the elements and for the determination of the species in water, soil and air. For this purpose hyphenated techniques, coupling chromatography to atomic spectroscopic methods, are often used so as to realize on-line pre-enrichment or separation and the determination of elemental species. For this purpose, GC, LC and SFC have been used (for a review see Dai and Jia).\(^{(508)}\) With this approach organics, metals and organometallic species have been determined in various types of water samples.

For organics, GC coupled to MS and to MIP AES have been shown to be complementary for screening tests. This has been shown e.g. for the case of atrazine, where a peak identification was possible from the elemental signal ratios for C, H, Cl, Br, N and S on the one hand and from library mass spectra on the other.\(^{(509)}\) Further, the power of detection of the GC/MIPAED technique for organics using empirical formula determinations, as required for screening in running water, could be considerably increased by preconcentration on LiChrolut EN\(^{®}\) microcartridges.\(^{(510)}\) Especially organohalogens have long been determined in waters by MIPOES.\(^{(511)}\) Cl-containing organics, such as trihalomethane\(^{(512)}\) and trichloroacetic acid,\(^{(513)}\) have long been determined by precolumn enrichment and microwave plasma detection. “Purge-and-trap” prior to pyrolysis with subsequent GC using MIP detection was used for the determination of 20 halogenated hydrocarbons in drinking water.\(^{(514)}\) For pesticide residue analysis, element-specific detection for C, H, N, O, S, P, F, Cl and Br with a commercially available GC/MIPAED system (Hewlett-Packard) was shown to be very useful.\(^{(515)}\) Pyrolysis, known from GC/MS work, could be shown to be useful also in the case of MIP/AED for improved elemental detection both for chlorinated and for S-containing species.\(^{(516)}\) In the latter case proteins and S-containing amino acids could be detected very sensitively after converting S into H\(_2\)S and trapping the latter by freezing.

In synthetic ocean water, metal determinations (Cr, Mn, In, V, Pb and Sr) could be performed by the direct introduction of aerosols produced by a MAK pneumatic nebulizer without the need for desolvation.\(^{(517)}\) For elements such as Pb a pre-enrichment as dithiocarbamate and direct GC/MIPAED were found to be very useful in improving the power of detection as required for the analysis of rain and tap water.\(^{(518)}\) For volatile and volatile compound-forming elements very sensitive detection also is possible. This has been shown for the case of I, which chemically could be volatilized from brines or seawater,\(^{(519)}\) for Hg, which could be determined with the CV technique and after Au amalgamation down to the nanograms per liter level in lake water,\(^{(520)}\) and for As, which could be determined in sewage sludge when using a CMP and HG.\(^{(521)}\)

Especially more recently much work has been done on the determination of organometallic species in water samples. Especially for organotin, organolead...
and organomercury compounds, derivatization was found very useful.\(^{[523]}\) Both ethylation and phenylation with sodium tetraethylborate or tetraphenylborate, respectively, and Grignard reactions are useful for converting the analytes into thermally better stable and more volatile compounds. Organolead species in this way could be determined in River Danube water down to the nanograms per milliliter level\(^{[524]}\) and organotin compounds in water from the Thermaikos Gulf.\(^{[525]}\) In the case of Sn, derivatization with tetraethyl borate could be performed on-line for the case of river water.\(^{[526]}\) For drinking water an extraction of 30 mL with hexane was found to be sufficient to allow the detection of organo-lead and -tin compounds, the latter down to the 40 ng L\(^{-1}\) level.\(^{[527]}\) Much work has been done on the detection of the organomercurials in water samples, as already mentioned for the case of seawater in early MIP work.\(^{[528]}\) Owing to the labile character of many organomercurials and organolead compounds, filtration through a dithiocarbamate-containing cartridge has been proposed and tested for pre-enrichment in the case of natural waters\(^{[529]}\) and seawater;\(^{[530]}\) however, it was found to be problematic for long storage. For integrated sample preparation and speciation, purge-and-trap injection GC is very useful. Here sodium tetraethylborate is added to the water sample and the mixture is purged with He while trapping the analytes at \(-100\) °C and applying subsequent flash desorption and GC analysis. Accordingly, organo-lead, -tin, and -mercury compounds could be determined in estuarine waters down to the nanograms per liter range.\(^{[531]}\) For organomercury determinations in water samples, adsorption of the derivatives on a nonpolar microcolumn also was applied.\(^{[532]}\) For the case of organoselenium compounds in water samples, purge-and-trap procedures were also found to be very useful.\(^{[533]}\)

The determination of organolead species in ice samples was also found to be interesting as it delivers archive data on the nature of Pb pollution. When using derivatization and solvent venting procedures, the analysis of Greenland ice was shown to be possible down to the femtograms per gram level.\(^{[534]}\)

The determination of traces of organometallic compounds in soils and sediments puts high requirements on the sample preparation. The determination of Pd in spent catalysts in waste from a production plant was found to be possible by acid extraction and analysis of the extracts by MIPOES using USN. In the extraction of soils with organic solvents, recoveries of organotin species were determined\(^{[535]}\) and the organo-lead, -tin, and -mercury analytes were derivatized with a Grignard reaction. As a soft extraction method for methylmercury determinations in sediments, supercritical fluid extraction with CO\(_2\) was found to be promising.\(^{[536]}\) \(^{15}\)N is an important tracer for studies on the N cycle in agriculture and it was shown that both \(^{14}\)N and \(^{15}\)N can be determined separately in soils by MIPOES on converting NH\(_3\) nitrogen into N\(_2\) with NaOBr and measuring the intensities of the N\(_2\) bandheads.\(^{[537]}\) Volatile arsenic compounds could be determined in soils after their thermal volatilization and MIPOES.\(^{[538]}\)

With respect to gas analysis, organobromine compounds and hydrogen bromide could be determined in car exhaust gases after trapping them on Tenax\(^{\text{R}}\) and applying thermal desorption with subsequent GC/MIPAED.\(^{[539]}\) Also low-molecular-weight S compounds could be determined in air with MIPOES.\(^{[540]}\) A direct determination of gaseous and particulate Pb in air could be performed with an air CMP\(^{[541]}\) and a detection limit of 5 \(\mu\)g m\(^{-3}\) was reported.

For the analysis of petroleum- and natural gas-related products, MIPOES is also of use.\(^{[542]}\) Organomercury species, for example, could be determined in natural gas using on-line amalgamation for trapping or solid-phase microextraction prior to GCMIPAED.\(^{[543]}\) and detection limits at the 0.2 \(\mu\)g L\(^{-1}\) level could be obtained for the various species.

### 7.3 On-line Monitoring

Because of the low capital and operating costs of microwave plasma discharges compared with ICPs, they are very useful for on-line monitoring purposes where metal concentrations in gas flows or in flowing liquids have to be monitored continuously. This growing need is introduced by the requirements for process control so as to optimize industrial processes with respect to product quality, costs and environmentally relevant emissions. Especially the cost effectiveness but also the fact that microwave plasmas in a number of cases can be operated with air makes them very attractive for on-line monitoring.

Microwave discharges have long been proposed for air quality monitoring.\(^{[544]}\) Their possibilities for the determination of Hg in molecular gases were investigated in the case of an MIP operated in a TM\(_{010}\) cavity according to Beenakker.\(^{[545]}\) When using a tangential flow torch, N\(_2\) loaded with Hg can be entered as outer gas and detection limits in the case of OES are in the 10 \(\mu\)g m\(^{-3}\) range. It was found that in view of possible applications of such a system for the on-line analysis of flue gases, considerable deterioration of the analytical signals occurred as a consequence of the presence of water vapor or molecular gases such as CO\(_2\) and SO\(_2\). It also could be shown that on-line speciation for Hg is possible. Indeed, by the use of a KCl-coated denuder (for HgCl\(_2\)) and an Au- or Ag-coated denuder (for metallic and oxidized Hg) placed in-line, the most relevant species can be separated.
MIP0ES, however, must still be optimized further so as to reach the detection limits of filter-based methods using determinations in decomposed filter residues by CVAAS, where a detection limit of 0.1 µg m⁻³ was obtained for Hg.\(^{(546)}\) Also for the determination of Hg in wastewater, MIP0ES subsequent to the volatilization of metallic Hg can be used and here a detection limit of 0.31 µg L⁻¹ has been reported.\(^{(547)}\)

The CMP, owing its stability, is much more appropriate for on-line measurements, as shown by lead determinations in air.\(^{(541)}\) This plasma can be operated with air only at a power of some ca. 100 W and the gas flows can be varied from 0.2 to several liters per minute, allowing for flexibility in sampling, which should be performed isokinetically with the flowing medium to be monitored. The air CMP also tolerated the uptake of large amounts of organics and with both wet and dry aerosols the excitation temperatures were above 5000 K. Rotational temperatures were about 4000 K,\(^{(32)}\) while the electron number densities were at the 10¹⁴ cm⁻³ level. With an air CMP operated at 600 W, detection limits for Cr, Cd, Pb, Co, Fe and Ni are at the 0.03–10 µg m⁻³ level but they increase by up to 10-fold when the water loading increases above 100 g m⁻³ or the CO₂ concentration increases to 20% (Table 8). As the air sampling certainly can still be improved, this especially shows that the CMP is a strong tool for on-line monitoring not only in complex gas mixtures such as flue gases but also for liquids, as the uptake of wet aerosols without the need for desolvation is possible.

### 7.4 Direct Solids Analysis

Different direct solid sampling techniques known from ICP work can also be directly used in the case of microwave plasmas. As the relevant techniques, such as SA, LA and ETV, deliver dry analyte vapors or aerosols, they do not even require any precautions in the case of low-power microwave discharges.

Direct sample insertion requires a more voluminous plasma to accommodate nanomicrosamples. For this technique the CMP could be used very successfully. In biological samples such as soils, tomato leaves and bovine liver, Cd could be determined by placing the solid samples in a W cup loaded in a graphite holder in the center tube of a quartz torch with two concentric tubes. With suitable temperature programming, absolute detection limits of 40 pg for Cd could be obtained.\(^{(549)}\) Steel samples could also be analyzed with the same set-up and Cr, Mn, Sn and Pb could be determined, Sn and Pb with detection limits of 0.08 and 5 µg g⁻¹, respectively. The water content of solid samples could also be determined with the aid of OES using a CMP.\(^{(550)}\) Here the solid samples are heated in a quartz crucible and the water evolved is carried with a He flow into the CMP, while measuring the line intensities of O and H. The technique has been applied to water determinations in biological samples (tuna fish, freeze-concentrated and dried orange juice), coal and CuSO₄·5H₂O.

Because of its small volume and low power, the MIP is only capable of evaporating very small particles (micrometer range) or of exciting vapors. This capacity can even be used for sizing particles in aerosol flows.\(^{(551)}\) Here particles are first sampled on a filter and then aspirated into an He MIP with the aid of a scanning nozzle. The emission signals are proportional to the mass of the particles and the wavelengths present in the spectrum provide information on their composition. As the particles enter the MIP one by one, the number of signals counted provides information on their number. The apparatus is commercially available and a number of industrial and environmental applications have been reported.

ETV can easily be used for the analysis of powdered biological samples with MIP0ES. Here a conventional GF can be used for sample volatilization and the lead vapor without overpressures suddenly occurring into the MIP.\(^{(552)}\) For sample dispensing, a powder pipet can be used with which samples of down to 2 mg can be dispensed reproducibly and a calibration can be performed by standard addition with solutions. After performing a simultaneous and time-resolved measurement of line and background intensities, Mn could be determined reliably in the 10–150 µg g⁻¹ range and detection limits of 0.07 µg g⁻¹ Cu, 0.5 µg g⁻¹ Fe and 0.2 µg g⁻¹ Mn could be obtained. A real-time background correction was found necessary as small sample amounts entering the plasma could be observed visually to change its form and excitation conditions.

SA is known to produce aerosols with particle sizes in the micrometer range, as described by Raeymaekers et al.\(^{(553)}\) The concentrations of analytes in the aerosol as a function of the sparking conditions are well representative of the composition of the solids, as investigated for steels, brass and aluminum samples. However, as shown by single-particle analysis with an electron microprobe, a redistribution of the elements over the different particle classes may occur. This may lead to matrix effects.

Table 8 Detection limits (µg m⁻³) using OES with an air CMP and different CO₂ concentrations; total gas flow = 1.2 L min⁻¹.\(^{(548)}\)
as shown in early spark ablation/inductively coupled plasma optical emission spectroscopy (SA/ICPOES) work on aluminum samples. Referring to Helmer and Walters, the production of particles in SA is very complex, as both large particles, which are deposited immediately besides the spark gap, and small transportable particles are formed in a spark. The formation results both from direct ablation and melting in the spark plasma and from vapor condensation. With an Ar carrier gas flow the aerosols obtained by SA can be transported reproducibly and with low memory effects into an MIP discharge. With the aid of vidicon detection, spectra from the material produced by microwave plasma discharge excitation could be observed, which were less complex than the spark spectra. In the case of a moderate-power MIP, the technique could be shown to be useful for the determination of Cr, Ni, Mn, Cu and Si in steel and of Fe, Si, Mg, Mn, Cu and Zn in aluminum alloys. The spark-ablated aerosols also could be led into an MPT, which is viewed axially or laterally with an optical spectrometer. After optimizing the gas flows in the ablation chamber and the MIP, detection limits were obtained which were higher than in the case of SA/ICPOES using a sequential spectrometer. However, probably the difference by one order of magnitude is due to the differences in the spectrometers used. Further, it could be shown that the precision and the linearity of the calibration curves could be considerably improved by using a matrix line as reference. A pulsed MIP could also be operated very successfully for the analysis of steels.

As a direct solids sampling technique, LA has the advantage that also for electrically nonconducting samples aerosols can be produced and that at the same time laterally resolved information can be obtained. Because of the availability of very robust Nd:YAG lasers with a reproducible power output from one laser pulse to another and the growing need for the direct characterization of electrically nonconducting samples such as plastics and ceramics, the technique has been investigated in detail and combined with various radiation and ion sources including microwave plasma discharges, as described as early as 1980. In the case of brass, it must be mentioned, however, that without carefully optimizing the working pressure and the laser parameters, selective volatilization can easily occur, as reflected by electron probe microanalysis in the crater, at the crater wall and of the ablated particles. As shown in Table 9, this contrasts with steel samples.

LA has developed into a mature procedure. When combining it with an MIP operated in a TM₀₁₀ resonator and when using a simultaneous echelle emission spectrometer with crossed dispersion and accordingly high resolving power, Be, Mg, Cr and Al could be determined in Cu, Ni and borax glass. High precision could be obtained when using internal standardization. Even from a single laser shot Na and Li could be determined in quartz with detection limits of 35 and 70 ng g⁻¹, respectively. Fluctuations in LA resulting from power changes or surface effects could be corrected for by applying scattering light measurements and on comparing an Ar ICP with an He MIP the latter was found to give the lowest background intensities. As for a few microseconds the plasma is briefly perturbed as a result of the laser pulse whereas the emission lasts for milliseconds in the case of an MIP operated at reduced pressure, it was proposed to perform time-resolved measurements. When applying time-gated detection of the emission spectra combined with internal standardization of the line intensities for both the main and trace elements in steel, Cu, Al and borax glass, a matrix-independent analysis was found to be possible. With LA coupled to MIPOES using a low-pressure plasma, traces of Mg, Al, Si and Fe also could be determined in high-temperature superconductors (YBa₂Cu₃O₇) and Na could be determined in GeO₂-doped quartz tubes down to 40 ng g⁻¹. Care must be taken to ensure an air-leak-free construction of the MIP source.

When using MIPs at higher power, direct powder injection could also be applied successfully, as shown by the example of coal analysis.\textsuperscript{567} C/H elemental ratios could be determined, but not Cl and S concentrations, when flushing the vials containing ground coal with He.

\section*{8 COMPARISON WITH OTHER METHODS AND OUTLOOK}

Compared with other plasma sources for chemical analysis, such as plasma arcs and ICPs, MIPs have some differences which make their analytical features understandable. First they are operated at frequencies in the gigahertz range. This makes it understandable that deviations from TE are more pronounced than in high-frequency or even in arc sources. Indeed, the electrons can easily take up the microwave energy rather than giving it to the much slower gas atoms and ions. These deviations from LTE are known to lead to higher line intensity ratios as described in pertinent discussions in the literature. This is responsible for their high absolute power of detection. Further, microwave plasmas can be small and can often be contained in capillaries. This leads to high analyte number densities. This, however, is not always most favorable in AES as the background intensities in the analytical zone are then relatively high. Therefore, the development of toroidal plasmas, such as that realized in a resonator according to Beenakker with quartz tubes having a 4 mm internal diameter, and the use of the MPT are very important, as in their sources the analytical zone has a lower temperature than the plasma-generating zones which are outside. Microwave discharges have been shown to be very useful atom reservoirs for AAS and AFS or LEI, because of the high analyte number densities. Indeed, these “zero-background” types of spectroscopy are not hampered by spectral background emission in the analytical zones.

In the case of MS analyses, the very small plasmas may not suffer from this drawback that limits OES, but also here larger plasmas with a better stabilized analytical zone may be advantageous so as to keep matrix influences resulting from changes in the plasma geometry low. Microwave plasmas also have the advantage over ICPs that they can easily be operated with He, which makes economic sense because of their low gas consumption. This makes microwave plasmas very useful for the determination and detection of nonmetals, which explains their success in speciation and in empirical formula determinations for organics. The fact that MIPs and especially the CMP can easily be operated on an air base only makes it very useful for on-line measurements. Indeed, here the operation costs really become low and as both wet and dry aerosols and gases can be sampled, both in process flows and exhaust gas flows, and also in wastewater, metals and nonmetals can be determined on-line. This makes microwave discharges very promising for environmental monitoring, e.g. in flue gases from waste incineration.

Microwave plasmas still have considerable potential for further development. Especially the variety of cavities which can be used for the production of different types of discharges with varying properties has hardly been exploited up to now. Here, both the demand for robust discharges with good sample uptake capacities also in the case of solvent-loaded aerosols, operation with both noble and molecular gases, the costs of operation and the ease of handling are important criteria. With respect to the last point, it was interesting how the need for retuning could be made superfluous in the case of the MPT by redesigning the device with respect to the coupler and dimensions as revealed by modeling.\textsuperscript{63}

A further trend in development lies in the miniaturization of MIP devices together with their use in combination with small spectrometers. Ideally, both the source and the spectrometer than could become plug-in accessories to be housed in computer racks. This point is of key importance for the wider use of microwave plasma detection in chromatography. Then the MIP surely could replace the conventional flame ionization detector (FID) and electron capture detector (ECD) much more easily and their capabilities for element-specific detection making the interpretation of chromatograms much easier could be more widely used.

The microwave discharges certainly should be improved with respect to their uptake of wet aerosols. Here, however, more powerful aerosol generation devices, which produce aerosols with a smaller droplet size, a narrower droplet size distribution and a better independence from the physical properties of the liquids are desirable, in addition to optimal adaption to the microwave plasmas. In this respect nebulization systems such as the DIN, HHPN, as introduced by Berndt,\textsuperscript{189} and also the straightforward design of nebulization chambers to be used are important. Indeed, these are prerogatives for making use of the small volume and thus the less disturbing properties of MIPs in LC detection as compared with the ICP.

Finally, as ionization sources for MS, microwave plasmas also have great potential, as here He can easily be used. This reduces the problems of interferences, especially in the lower mass range as compared with inductively coupled plasma mass spectrometry (ICPMS). With molecular gases toroidal plasmas can successfully be operated, as shown by Leis and Broekaert.\textsuperscript{67} In atomic emission they suffer from a number of limitations as a result of background intensities, but this is not the case to the same extent when using them as ion sources for MS.

1 INTRODUCTION

The mathematical and statistical analysis of chemical data is generally discussed collectively under the term "chemometrics." Chemometrics is an interfacial field, lying between the more established fields of chemistry, chemical engineering, statistics, electrical engineering, and computer science. Like many interfaces, there is uncertainty in the exact location of the borders. Many of the borders between chemometrics and the other disciplines are unclear or even disputed, and there are even differences of opinion on the correct pronunciation of the word "chemometrics," but most agree that the goals of chemometrics include the development of mathematical and statistical methods for extracting and representing chemically relevant information from chemical data. The most important applications of chemometrics come in the discovery of the quantitative relationships between chemical measurements and properties and the qualitative modeling and classification of the behavior of chemical systems. A sizeable fraction of the applications of chemometrics have been reported in analytical chemistry and in the closely related field of process analytical chemistry, where the main goal is often the quantitative estimation of chemical concentrations of mixtures from multivariate physical or chemical measurements obtained on those mixtures. Applications of chemometrics to problems in the fields of chemical and electrical engineering are far less numerous, and most of these have dealt with applications of chemometric methods in connection with process monitoring and control or for signal processing.

The field of chemometrics has a similarly uncertain beginning. Several prominent workers in chemometrics, when interviewed by Geladi and Esbensen, reported a wide range of dates and people as being the first to do what is now called chemometrics. The dates cited by these workers ranged from about 1976 to as early as 1908. The early date cited here is important, because it focuses our attention on the fact that researchers have done chemometrics from the point when substantial chemical data began to become available. Gossett published his work for Guinness in 1908. Youden and Wernimont did data analysis and wrote articles and books on quality control in the 1940s and 1950s. There was some interest in their work in chemistry for a good while, but much of that died away by the early 1960s. Box, now a famous statistician, also started as a research chemist who got involved with analysis of plant data. Substantial support by chemists for analysis of chemical data as a sub-field of chemistry failed to occur during these times, and interest died out in chemistry. The individual workers doing such analyses mostly went in the direction of statistics because there they found numbers, interest and acceptance. Statisticians then were a relatively small group too, but they were vastly more numerous than the chemical data analysis community, and they had enough desire to broaden their field that these more applied people were welcomed.

Only in the late 1960s and early 1970s, when automated data collection and computation had both gotten much easier, did the need in chemistry again arise for the field. Factors that led to the formation of the field were the press of too much data, the increasing availability of improved mainframe computers with new statistical software packages, the changing attitudes in the statistics and analytical chemistry communities, and the need for answers. A few researchers realized very early that mathematical methods for finding the relations between measured variables and relations between measurements and latent variables could help in finding the information embedded in large amounts of data. These ideas were revolutionary, in that they offered completely new ways of examining the complex, multivariate data sets that were beginning to appear in chemical studies. Because these methods provided useful answers to questions posed by chemists studying large data sets, they attracted a great deal of interest. Very quickly, a sizeable number of...
researchers were exploring the limits of this new approach to data analysis, and the field now known as chemometrics came to be. The field's very name, the publication of the early Chemometrics Newsletter and the formation of the Society for Chemometrics were early indicators of the eagerness with which the field was accepted at first. Howery and Hirsch (5) have briefly summarized the early days of chemometrics.

Changes to the fields of analytical chemistry and statistics also helped shape the new sub-field's goals and make-up. The huge increase in the number and sophistication of chemical instruments made available the chemical data that drives chemometrics. It also changed analytical chemistry into an instrument-oriented field, with more emphasis on the physical chemistry of measurements and less on the classical elements of equilibrium theory. Analytical chemists went from being practitioners of the meticulous art of classical analysis, where the quirks of solution-phase chemical reactions were either used or avoided, to specialist workers focusing on the construction and use of a single, increasingly complex instrument that, in ideal cases, made measurement of some analyte species concentration simpler and more sensitive through the application of ideas from physical chemistry, as well as physics and engineering. (5) In that process, these chemists subscribed – perhaps unknowingly – to the idea of latent relationships in data. Finding these latent relationships in data is often the goal of a chemometric study.

The increased sophistication of the computer also changed statistics, though not as much as might have been expected. The field of statistics has always had an uneasy time with its close relationship with mathematics. The 1930s and 1940s saw rapid progress in the field of statistics. Mathematical statisticians made great progress by using properties of distributions to solve a wide range of problems concerned with classical modeling. The more applied statisticians tended to take a Bayesian approach to problems when developing their applications of these newer methods in the many areas where data analysis was applied. The analysis of mostly chemical data from the medical sciences was an area of particular focus because a large amount of univariate data was routinely available.

Economics and psychology, two areas whose data sets also involve latent relationships, but with far fewer variables than were routinely being generated by the new chemical instruments, were, like chemometrics, left to those with an interest in nonclassical modeling methods.

2 SOFT MODELING IN LATENT VARIABLES

Many of the methods employed in chemometrics are based on the concept of soft modeling, a linear modeling method that originated in the field of multivariate statistical analysis but which has become synonymous with the term “chemometrics.” The focus of the soft modeling method on the properties of the signal rather than on the noise help to distinguish chemometrics from statistics, where the emphasis is usually on the structure and properties of the error term. Chemists often confuse the two fields. It is worthy of note that, while chemometrics brought many statistical concepts to chemical applications early in its history, in recent years the transfer of information and technology has been from chemometrics to other fields, including statistics. Soft modeling is an area where advances from chemometrics are now aiding a wide range of diverse fields, from remote sensing to psychology.

Because of the heavy emphasis on soft modeling in chemometrics, the field developed around an algorithmic rather than theoretical framework, an attribute that is only now beginning to change. Discussions of soft modeling in current literature are more likely to focus on the linear algebraic theory of the modeling than on the specific steps needed to form the model.

To understand the field’s present status and direction, it is necessary to have an appreciation for some of the key approaches and assumptions of soft modeling, as these underlie the logic of many of the chemometric methods (6). More details are available in the Encyclopedia article Soft Modeling of Analytical Data to follow, so it is appropriate to provide only an overview here.

Traditionally, modeling in chemistry and chemical engineering has been done using “first-principles” (hard) models. A hard model is one that describes the system in terms of mathematical relationships developed using the measurement variables as independent variables and the desired outputs as dependent variables. Because chemical systems studied are complex, the hard modeling used in chemistry has either been applied to simplified systems or has involved either limiting “laws” or other approximations and restrictions to the region of application of the hard model. Soft modeling sees the problem from an entirely different logical perspective: it presumes that the chemical system under study is complex, and that it is not possible or economically feasible to adequately describe the behavior of the system using a hard model. The soft model is based on variation and correlation in the data, as captured in a covariance matrix – which can be thought of as a measure of the overall fluctuation in each independent variable present in the data set, as well as the variable-variable interactions.

A set of orthogonal components made from linear combinations of the independent variables is created to describe independent sources of the observed variation in the covariance matrix created from the data set analyzed,
The strength of soft modeling with latent variables is that systematic sources of variation in the data do not go unmodeled, as they might under hard models developed with inadequate theory. Relationships in data can be modeled even when the existing theory is incomplete, wrong, or even missing. The ability to model linear relationships in the absence of suitable theory has made soft modeling an attractive approach for a wide range of problems in applied and analytical chemistry, including modeling of quantitative relationships in spectroscopy, quantitative structure–property relationships, and many other quantitative modeling scenarios. Soft modeling with latent variables also has uses in semi-quantitative modeling, where latent variables can be used to group or to classify samples by some latent property. Examination of the latent variables can often provide insights into the chemistry behind the observations. And, because latent variables are linear combinations of what may be many measurements, they offer a way to screen measurements for appropriateness and impact on the modeling. For this reason, soft modeling in latent variables is often used to discover relationships in data.

Soft modeling comes with several inherent defects, however. The most serious is that the latent variables created in the soft modeling are local to the data set analyzed. The soft model developed explains the variation seen in the data set used to create it. Unfortunately, quantitative modeling often requires a predictive model, and there is strong incentive to take a soft model developed on one set of data for use on an entirely different set. Any use of this model on new data is an extrapolation and, unless great care is taken in collecting and analyzing the data, the soft model may have little predictive use. Because the soft model defines a truncated mathematical basis for a series of measurements, it is possible to create a soft model on one set of data and to use it on a closely related set. To make this possible, though, the truncated basis defining the latent variables developed in the soft model must span the bases defining any new set of experimental data subjected to the model. The subtle and not-so-subtle consequences of this requirement force the user of soft models to consider the experimental design of data sets and the sensitivity of the models to individual samples to a degree that goes far beyond that done with more traditional modeling methods.

A second difficulty with soft modeling arises from the fact that the latent variables describe orthogonal mathematical effects, and not physical effects. Most physical effects show high correlation between measurements, especially between adjacent measurement channels (e.g., individual variable “channels” in spectra or chromatograms). For example, suppose that in a chemical calibration, the varying amounts of two different compounds with different spectra are responsible for the two different sources of variation in the analytical response. These two chemically distinct sources may not be mathematically independent, however, because of the redundant nature of most multichannel responses measured with chemical instrumentation. Described in terms of latent variables, though, the sources must be mathematically independent. The result is the mixing of separate, chemically significant effects in each of the latent variables and the spread of these effects over several latent variables. The latent variables describe variation in measurements rather than some easily understood measurement phenomenon, such as the absorbance at a particular wavelength. Direct interpretation of the chemical significance of these latent variables is difficult or impossible. Usually, conversion of mathematically significant effects as evidenced in the latent variables surviving after truncation of the soft model back to physically significant effects is needed to extract chemically relevant

\[
X = UV^T
\]  

where matrix \( V \), the loadings of \( X \), contains the linear combinations of the original measurement variables that define the new variation-based coordinate system spanning the data in \( X \), and matrix \( U \), called the scores of \( X \), contains the coordinates of the data \( X \) in that variation-based coordinate system.\(^7\)

These linear combinations of the measured variables are called latent variables because they are derived rather than measured. The latent variables extracted to describe a data set are ordered in terms of the size of the independent sources of variation that they explain: the first latent variable explains the largest independent source of variance in the data, the second latent variable the second largest, and so on, until all variation in the data set is accounted for by one of the linear combinations of the measurements. Generally, re-expression of the data set \( X \) in terms of latent variables is not useful unless a decision is also made on the number of latent variables that are needed to adequately explain the systematic variation in the data \( X \).

Any correlation between the dependent variable(s) and these latent variables is captured by means of a regression model. The regression step can be done after the creation of latent variables for the independent variables and the removal of sources of variation believed to be unrelated to the systematic effects under study. Building a regression model by first soft-modeling and truncating the independent (measured) variables is known as principal components regression (PCR) in statistics and chemometrics (or it can be done in concert with the extraction of the latent variables using a modeling method known as partial least squares (PLS) regression).

The strength of soft modeling with latent variables is that systematic sources of variation in the data do not go unmodeled, as they might under hard models developed with inadequate theory. Relationships in data can be modeled even when the existing theory is incomplete, wrong, or even missing. The ability to model linear relationships in the absence of suitable theory has made soft modeling an attractive approach for a wide range of problems in applied and analytical chemistry, including modeling of quantitative relationships in spectroscopy, quantitative structure–property relationships, and many other quantitative modeling scenarios. Soft modeling with latent variables also has uses in semi-quantitative modeling, where latent variables can be used to group or to classify samples by some latent property. Examination of the latent variables can often provide insights into the chemistry behind the observations. And, because latent variables are linear combinations of what may be many
information. In essence, the conversion needed is an oblique rotation of orthogonal basis defined by the latent variables into the nonorthogonal basis defined by the nature of the physically significant information desired. Without external constraints or some prior knowledge of the solution, constraining the large number of possible rotations is impossible in many cases. The conversion of a mathematically useful latent variable set to a chemically relevant basis is therefore a stumbling block in getting usable chemical information from the soft modeling. This fact more than anything limits the use of chemometrics to those secure enough in the mathematics to apply it without many of the usual “safety lines” associated with visual interpretation or simple statistical inference (confidence intervals, etc.).

Another defect in soft modeling is the lack of an easy route to distinguish the sources of variation attributable to systematic, chemical effects in the data from other sources of variation. Accidental correlations arising between systematic variation in the data and various kinds of noise present either in the measurements themselves or in the taking of the data can corrupt the latent variables. One consequence of this accidental correlation is the aliasing of measurement variables weighted heavily in the latent variable; it is possible to see increased or decreased weights given measurements in a latent variable as a consequence of noise-induced artifactual correlation with another measurement variable with large variation. These artifacts in the correlation and variation present in the data set frustrate the modeling effort in several ways. First, when present, accidental correlation induced by noise effects can make difficult the direct interpretation of the latent variables, an important part in extracting information from the soft model. Second, the presence of the incorrect weighting of the measurement variables in the latent variables can corrupt the rotation of latent variables back into chemically significant information presented in terms of the original measurement variables. Third, the noise-related artifacts complicate statistical decisions on the number of latent variables needed to describe a systematic effect in data, a key part of the development of the soft model.

3 CURRENT DIRECTIONS IN CHEMOMETRICS

In view of the importance of soft modeling to the study of complex chemical systems, most standard chemometric methods rely heavily on soft modeling in one form or another and make full use of its advantages. Advances in these chemometric methods often come in the development of new algorithms or new ways of using older methods that can either ameliorate or avoid the above-mentioned difficulties associated with soft modeling.

4 MULTIVARIATE (FIRST-ORDER) CALIBRATION

The best-known examples of the use of new algorithms to make use of soft modeling practical come in the area of multivariate calibration. This is the subject of the Encyclopedia article Multivariate Calibration of Analytical Data. An overview is provided here.

Here, the PCR algorithm and later the PLS algorithm were modified and put to use in improving the extraction of quantitative information such as concentrations from analytical responses. One modification came in that the soft modeling was done on an inverse relationship between responses and concentration, namely Equation (2)

\[ C = RB \] (2)

where \( C \) is an \( m \times n \) matrix of concentrations, \( R \) is an \( m \times p \) matrix of responses, and \( B \) is a \( p \times n \) matrix describing the calibration relationship. Equation (2) is an inverse Beer’s law relation, as it implies that concentration \( C \) carries the error and is dependent on the response variables in \( R \). By soft modeling the response \( R \) (and \( C \) with PLS), then truncating the soft model to decrease the variance unrelated to the calibration relationship, a useful calibration model results. This model has the benefit of being suited to predict one component in a calibrated mixture.\(^{(8)}\)

The most widely known success of first-order calibration methods has come in near-infrared (NIR) spectrometry, a fairly general analytical measurement that is often useless for direct quantitative measurements because of the lack of specificity of NIR bands.\(^{(9,10)}\) Efforts to enhance the specificity or selectivity of analytical instrumentation, especially spectroscopic and chromatographic instrumentation, continue to make up a sizable fraction of chemometric research. Multivariate calibration using PLS for the modeling of the inverse response–concentration relationship has become commonplace in the last 10 years, and these techniques have begun to be embraced by industrial chemists and chemical engineers.\(^{(11)}\) Published applications of multivariate calibration abound, as is clear from the number of citations in the Fundamental Reviews reported over the last 10 years,\(^{(12)}\) but it is the author’s experience that many more applications of multivariate calibration are put into practice than are reported. A good, short introduction to PLS theory and coding is also available.\(^{(13,14)}\)
The current trend in first-order calibration is to explain the calibration in terms of the net analyte signal.\(^{15,16}\)

5 SECOND- AND HIGHER-ORDER CALIBRATION

Second-order calibration, where the analytical response gives rise to a matrix rather than a vector of data, is a very active area of research at present. This area is the subject of the Encyclopedia article Second-order Calibration and Higher, so again, only an overview is provided here. There are two reasons for the interest. One is practical: a large number of analytical measurements give rise to a matrix of data (e.g. a liquid chromatographic separation monitored with a diode-array detector). There is also a theoretical “second-order advantage” in using these data in a calibration, in that the mathematics permits analysis of a calibrated component in the presence of an uncalibrated interference.\(^{17}\)

The analysis of higher-order chemical data – that is, data with dimension higher than one – involves a choice of the way that the data are unfolded to make matrices of data (where the rows are defined by the individual samples and the columns by the components of the one-dimensional measurements) for more conventional matrix-oriented analysis. Smilde has reviewed different unfolding methods, including the various Tucker unfolding schemes and parallel factor analysis (PARAFAC) modeling, and offered an explanation of the history and applications of higher-order analysis.\(^{18}\) As in first-order data analysis, early chemometrics work on higher-order data has benefited from porting of the substantial work on three-way methods published in statistics, psychometrics, and related fields. But, as with analysis of first-order data, the maturation of chemometrics research has led to significant contributions by chemometricians to this approach to data analysis.

Like multivariate calibration of first-order data, higher-order analysis is also based on soft modeling. It is no surprise that it carries some of the defects inherent in soft modeling, including sensitivity to noise, difficulty in getting the correct model size (the rank here) and problems in assuring the match of bases. There are some important differences, however: the rank annihilation method deals with information in multiple measurement dimensions, and it is far less susceptible to the effect of an interference that shows in a prediction sample but not in any calibration sample. Higher-order calibration is very dependent on a good match of the calibration model with the response data to be determined.

6 NONLINEAR METHODS

The history of measurement chemistry is filled with studies of linear systems and of efforts to make those nonlinear systems studied linear enough for examination by linear methods. It is therefore not surprising that relatively little effort has been placed on the systematic study of nonlinear methods as applied to chemical calibrations. The large majority of studies of nonlinear systems have been done using nonlinear causal models, because methods of nonlinear soft modeling developed to date require the underlying presence of specific nonlinear functional forms (e.g. quadratic relationships for loadings) and have not proved useful in practice.

Recent interest in soft modeling nonlinear relationships has centered on the use of neural networks. Artificial neural networks (ANNs), a modeling method that does not presume any underlying relationship in the data, have received some attention for the calibration of nonlinear chemical systems and have been used for modeling a number of chemical processes with success. An ANN models the relationship between the input independent variables and the output dependent variables by using weighted sums of transforms usually based on a sigmoid function or the tanh function, a close relative. These transforms are capable of describing very complex relationships between the independent and the dependent variables. According to theory, a three-layer net with sigmoid transfer function in the hidden layer and linear transfer function in the output layer can model any continuous function.\(^{19}\) The modeling is done by first establishing the topology of the network model, i.e. number of layers of nodes to be used, the number of nodes in each layer, and the transform operation used in each layer. Finding an appropriate topology is a fairly straightforward but time-consuming process. Generally, a number of possible candidate topologies are tried – these can be found by simple enumeration or by more sophisticated methods such as genetic algorithms – and the topologies giving the best results are kept for further analysis and optimization.

7 SEMI-QUANTITATIVE METHODS USING SOFT MODELING

In many studies, the goal is not quantitative, indirect measurement of one or more known, calibrated chemical species in a series of mixtures. The goal may be discovery of what chemical species are involved in a dynamic system, or possibly discovery of the number of species changing in that system. It may just be an objective measure that the dynamic system has not changed in its overall make-up. Chemometric methods based on soft-modeling of the
multivariate sensor measurements taken on these systems are well suited to obtaining information on the identity and number of chemical species.

When less is known about a data set, self-modeling can be attempted. The loadings used to describe a set of data are rotated to find another set of axes that has physical significance. In this case, less may be known about the composition of the system under study, and the number of possible rotations is infinite. External constraints such as all positive spectra and all positive amounts of species are needed to help limit the search to the space between the convex hulls defined by the different constraints. It is now known that the solutions are found near the apexes of the convex hulls, but there still is no systematic means to map out convex hulls and locate their apexes in the presence of noise and confounding effects. SIMPLISMA, one popular method for self-modeling, uses a visual examination to help find suitable rotations of the soft model. The solutions that result from this self-modeling are subject to uncertainty unless each species has a signature that is independent of the others at one or more of the sensors used to collect the multivariate set. The more similar the species’ true responses over the sensor set used, the larger the uncertainty in the self-modeled responses for these species will tend to be.

Often, self-modeling is needed because of a lack of solid information on the composition of the system, but the data are collected in such a way that ensures their serial correlation in both the sensor axis and another axis, often time. In these cases, the additional correlation offers an additional constraint that helps to remove ambiguity in the rotated solution. Now, it is possible to develop a series of soft models that evolve as the data evolves in time, in both the forward (increasing time) and backward (decreasing time) directions. Tracking of the number of significant principal components in the soft models over the time axis permits an estimate of the number of species that vary over the data set, as well as where it is in the data that the different species enter into the chemical system’s response. Rotation of the soft model to simultaneously describe both the response and the time-dependent data axes, subject to constraints in spectra and amounts, gives semiquantitative estimates of pure responses and relative amounts. Malinowski reviewed early work showing that this modeling approach can be used to discover relationships in data.

8 CLASSIFICATION AND CLUSTERING OF CHEMICAL DATA

It may be that there is grouping of the samples in the data according to some latent property. Often, a set of data is heterogeneous, in that the samples clump together rather than spread evenly over the multivariate space. Building a single PLS regression model on the full set of multivariate data is inappropriate because the variation captured in the modeling will be heavily influenced by variation between groups of data and will be less influenced by the variation between the independent and dependent variables. In these cases, a grouping step is needed before regression modeling to ensure that a homogeneous structure is present in some subset of the data prior to modeling this portion of the data. If a multivariate grouping structure present in the data can be guessed or determined, separate soft models can be developed for each group in the data.

Once grouping is decided, separate soft models can be built for each of the groups. Soft modeling can be used to develop class regression models for different values of the latent property. New data can be classified into the appropriate group on the basis of the distance of the new data to each of the class models. An F-test is used to decide on membership, again using residual variance in the fit and in the model. The SIMCA method focuses on modeling the classes rather than on finding an optimal classifier. By examining the mathematics behind SIMCA, it has become apparent that there may be better classifiers, depending on the structure of the data.

Current research in soft modeling for semiquantitative modeling has as an emphasis the removal of many of the problems associated with soft modeling that carry over to self-modeling. Making the evolving factor analysis methods work more reliably is a major focus of research, as are improved methods for getting self-modeling to work on many systems. Background and current research in classification methods are discussed in the Encyclopedia article Clustering and Classification of Analytical Data.

9 SIGNAL PROCESSING METHODS

Since the initial days of chemometrics, signal processing has long been a focus. Initially, the aim was noise reduction through smoothing off-line, but in recent times, the aim of signal processing has focused more on real-time data enhancement through filtering or on real-time control of a process through use of real-time data. Details are available in the Encyclopedia article Signal Processing in Analytical Chemistry. As this area has evolved, the interest of analytical chemists has waned while interest from chemical engineers and process chemists has increased substantially.
10 CLASSICAL AND NONCLASSICAL OPTIMIZATION METHODS

Chemometrics is mostly focused on data analysis but one aim has been the improvement of a process or system producing the data. Chemometrics has long been involved in process optimization, from the evolutionary optimization schemes of Box to the Simplex optimization methods perfected by Deming. Newer work on genetic algorithms and simulated annealing continue the advancement of optimization methods. The Encyclopedia article Classical and Nonclassical Optimization Methods discusses these optimizers.

11 KEY REVIEWS OF THE FIELD OF CHEMOMETRICS

Because of its early, close association with the field of analytical chemistry, the field of chemometrics has received frequent and thorough review in that field’s literature. Beginning in 1976, a detailed review of the methodology and practice of data analysis in chemistry has appeared in the biennial Fundamental Reviews issue of the journal Analytical Chemistry (the most recent as of this writing is that of Lavine12). These reviews provide a comprehensive analysis of the state of chemometrics and, when examined together, also provide a glimpse at the evolution of concepts in chemometrics over the past 10 years. Along with the reviews of basic research in chemometrics, three major reviews on chemometrics applied to problems arising in process analytical chemistry also have appeared in the Applications Reviews issue of Analytical Chemistry.

REFERENCES

Optimization problems are abundant in analytical chemistry, examples being the determination of optimal conditions for experiments or optimal settings for instruments. In general, all the required information should be obtained from as few experiments as possible. Classical techniques such as response surface models or simplex optimization are often used. These techniques, which can be very efficient in cases where the underlying assumptions are fulfilled, are called “strong” methods.

With the advent of the computer in the laboratory, a new class of optimization problems arose which could not be tackled with the standard methodologies. For these search-type problems, new strategies such as simulated annealing (SA) and genetic algorithms (GA) are applied. Although these are not guaranteed to give the optimal result, in almost all cases they are able to find very good solutions where other techniques fail completely. These methods find themselves in an intermediate position between the strong methods, mentioned above, and weak methods, where hardly any assumptions are made.

This article provides an overview of classical and nonclassical optimization techniques, and stresses the differences in their areas of application. The key ideas are highlighted and references to important publications are given.

1 INTRODUCTION

As in all empirical sciences, optimization problems are abundant in chemistry, and have been since the very first alchemist experiments. In the synthesis of gold from lesser substances, every conceivable variation of ingredients and experimental conditions was tried and eventually rejected. Sometimes these experiments were conducted in a very systematic way, sometimes random, sometimes somewhere in between. Although the main goal was never achieved, a lot was learned from these early experiments.

In the modern laboratory, the advent of complicated instruments controlled by computers has changed the nature of the problems faced by the chemist. Whereas the actual doing of the experiment used to be a major limiting factor in obtaining relevant information, and therefore warranted a large investment in time and energy to be designed and executed, in the modern laboratory experiments can be performed in a fast, reproducible way. For the sake of ever higher performance requirements, dictated by economic reasons, systematic optimizations are performed in all chemical laboratories, often consisting of hundreds or thousands of experiments.

Optimization is the search for a maximum or minimum in the value of a certain response function. For example, the yield of a chemical reaction is a function of several variables, such as concentrations of components in the mixture and physical characteristics such as temperature and pressure. The relationship between these variables and the response function (the yield) is unknown, but it can be sampled by performing experiments. The conditions in these experiments can be carefully selected by using knowledge (section 2.2) and, depending on the outcome, new experiments may be performed.

Such optimizations are typically performed in an iterative fashion (Figure 1). The search is started either from one or more random positions or from a set of points, picked according to some criterion. In the evaluation stage, the quality of the current point(s) is assessed by experiments. Several criteria may be used to stop the optimization, such as the number of experiments, or the quality of the solutions found so far. If no stopping
The most well-known method is SA. It is applied in computational optimization problems. The other two categories between chance and information. As they typically require a large number of experiments, they are often rejected than good solutions, but traditionally each optimization method uses its own particular selection scheme. Finally, in the generation of new trial solutions, strong methods use moves defined a priori by the user; intermediate methods usually apply a method-specific and/or problem-specific mechanism.

In cases where the response is an error value, as in curve-fitting applications, the optimal value is zero and all other response values are larger than zero. In many other applications the response variable is maximized, such as the yield of a chemical reaction. This article does not distinguish between these two cases. The examples given always relate to minimization problems without loss of generality.

1.1 Local and Global Optimality

To clarify the concepts of local and global optimality, the map of a mountain landscape, in which lines indicate regions of similar response, is often used as a metaphor. The peak of a mountain always is a local optimum, because in its direct neighborhood there are no higher places. However, only the peak of the highest mountain is the global optimum. In many optimization problems, finding the global optimum is the challenge, and the presence of many local optima complicates the problem significantly. In the same vein, local optimizers are methods that always find the (usually local) optimum near the starting position, and global optimizers are methods that end up at the highest peak, no matter where the search started from.

Many methods utilize a sense of direction in which to proceed. Steepest ascent/descent methods (discussed below) choose the direction in which most short-term gains can be made. These invariably end up at the nearest local optimum, and are therefore very bad global optimizers. However, techniques that have a better search behavior can also be led astray. Problems in which the global optimum is located in another area, as suggested by the slope of the landscape, are described as deceptive, and much research has been devoted to these. It should be noted that no method guarantees finding the global solution in finite time.

1.2 Problem Types

Several different problem types can be distinguished. By far the most common in analytical chemistry is the numerical problem, where for a number of parameters optimal values must be found. These parameters might be settings for a chromatograph or another instrument, or coefficients in a nonlinear equation describing a curve. The parameters may interact, or may be constrained to certain regions, and the resulting problem landscape may therefore be quite complex.

The second type of problem is formed by combinatorial problems. The complexity of this kind of problem often

![Figure 1 The basic iterative optimization cycle.](image-url)
is huge; most are nonpolynomial (NP)-complete, an indication meaning that when the size of the problem grows, the time needed to evaluate all possible solutions increases faster than the polynomial. In practice this means that even for small problems evaluating all possibilities is completely impossible. This also implies that only in special cases it is possible to know whether an optimum is truly a global optimum. Two basic forms can be distinguished: nonordered and ordered problems. A well-known example of nonordered problems is subset selection, which is a common issue in calibration and classification procedures. The problem relates to which subset of all available variables should be included in the statistical model. Not only does a small number of variables in model building lead to more robust and parsimonious models, it also may decrease experimental effort. Examples include wavelength selection from IR (infrared) spectra and variable selection in quantitative structure–activity relationship (QSAR) modeling, where a small set of relevant descriptors is to be selected from a potentially very large list.

Ordered combinatorial problems are also called sequential or scheduling problems. They are not so common in (analytical) chemistry but of tremendous importance in operations research, for example. The question is to put a set of objects in the optimal order, or in more than one dimension, at the optimal location. The traveling salesperson problem is a well-known example; microchip design and scheduling of analyses in a routine laboratory belong to this category. Just as problems from the previous class, sequential problems are more often than not NP-complete.

1.3 Example Problem: Fitting Laser-induced Fluorescence Spectra

An example used throughout this article concerns the description of laser-induced fluorescence (LIF) spectra of organic molecules.\(^5\) This kind of spectroscopy can provide much information on the structure and dynamics of molecules and molecular complexes in ground states as well as excited states. The experimental spectrum of benzimidazole is shown in Figure 2.

Hundreds of well-resolved peaks can be seen, whose positions and intensities depend on a small number of parameters. Some of these parameters are related to experimental conditions such as temperature; others are related to quantum-chemical properties such as rotational constants. For small molecules, the spectra can be interpreted and in this way a set of valid parameters is found. However, for larger molecules the number of possibilities quickly becomes too large and one is forced to resort to search methods. For a given set of parameters the theoretical spectrum for a molecule, can be calculated, and so the agreement between theory and experiment can be used to assess the validity of the parameter set. The
goal of optimization is to find parameters that yield a good approximation to the experimental spectrum. The difference is expressed as the root mean square (RMS) error.

In Figure 3 the RMS response surface is plotted if two parameters, the rotational constants around the two main axes, $A$ and $B$, are systematically varied. All other parameters are kept constant at their true levels. This response surface is used throughout the article. Note that the set-up where only $A$ and $B$ are optimized is only a toy problem, although the contour lines are not very smooth. The real, high-dimensional optimization problem is much more difficult.

1.4 Criteria for Optimization

In an optimization problem a minimum or a maximum value is sought for a response variable as a function of problem parameters that can be controlled by the user. The extent to which these parameters can be controlled determines the precision of the outcome. It is of course senseless to try and optimize beyond experimental error; nevertheless, it is easy to forget the obvious.

Whereas the previous considerations concerned noise in the response value, there is also the case where the parameters can be influenced by noise. Moreover, if a small change in optimal parameter settings (e.g. noise) leads to a drastic decrease in product quality, it may be useful to look not for the optimal solution but for solutions which are acceptable and not so sensitive to small deviations from optimality. In an industrial context robust and good solutions are often of greater interest than the very best solution, which may be unstable.

In other cases solutions proposed by an optimization algorithm may be physically impossible or economically undesirable. These constraints are not always easy to define. If that is the case, one alternative is to generate several solutions and pick from those the ones that least violate the boundary conditions.

Good optimization procedures should yield the desired information in a fast, reproducible, and reliable way. This means that repeated application should yield more or less the same answers or answers of the same quality. In some cases it may be important that all acceptable solutions are found, in other cases it is more important that the global optimum is found or that at least one good solution is found within time or cost constraints. These aspects are to some extent determined by the problem at hand.

1.5 Multicriteria Optimization

If additional constraints can be defined, often in terms of costs, it may be a good idea to include them in the response from the experiments. There are several ways of doing this, the simplest of which is a weighted sum of several response variables. However, the weights need to be set to realistic values and in some cases this requires quite a bit of fine tuning. Another approach is to consider several response variables at a time. One solution then dominates another if it is better at one or more of the response variables while not being worse for all other criteria. This is called Pareto optimality, after the Italian economist Vilfredo Pareto. The result is a set of solutions that dominate other solutions at least for a number of variables. The user than has to make the trade-off between optimality in one variable versus optimality in the other. Especially with a small number of responses it may be that a useful Pareto-optimal set of solutions can be found.

Optimization problems where the robustness of the solution is important form a good example of the possibilities of multicriteria optimization. Then one criterion is the quality of the optimum and the other the sensitivity of the response to small changes in the parameters (Figure 4). Fifty random samples were taken from the contour surface of Figure 3, and the RMS error ($x$-axis) is plotted against the difference in RMS value with the surrounding points ($y$-axis). The smaller this RMS difference, the more robust the solution. A front of Pareto-optimal solutions delimits a cloud of possible solutions. Note that the point with the lowest error (number 44) is not very robust, so in cases where robustness is important solution 7 might be a better alternative.

2 STRONG METHODS

Strong methods assume a certain structure in the solution space, such as a quadratic response surface or only
one optimum. If the assumptions are correct, these methods are fast and reliable. The main problem is that if the assumptions are not correct, these methods will not find the global optimum even if the number of experiments is increased drastically. In difficult optimization problems they are often used for the last part of the optimization, where the approximate global optimum has been identified and the exact location still must be found. Especially in low-dimensional optimization problems these methods are often very suitable. Examples include optimization in organic synthesis\cite{4,5} and method development in high-performance liquid chromatography (HPLC).\cite{6,7}

2.1 Gradient-based Optimization

The most intuitive methods of this class rely on an accurate estimate of the local gradient, and proceeding in the steepest direction. Depending on whether we are dealing with a minimization or maximization problem, the method is called “steepest descent” or “steepest ascent”, respectively.

The simplest and rather naive form is to assess the quality of neighboring points and, if there are better points, to proceed towards the best of these. Then, new neighboring points are evaluated and this process continues until there is no neighbor better than the current point. This process is depicted in Figure 5, using the error surface from Figure 3. Clearly, only from one of the 16 starting points the global optimum is located. The other starting points lead to (sometimes even quite bad) local optima. Each optimum has its own basin of attraction, indicating that any steepest descent search starting from a point within that basin will end up at that particular optimum. This, of course, is the definition of a local search method.

In some cases, especially those where the landscape being searched looks like a long narrow valley (in the case of minimization), steepest descent does very poorly. Unless the valley is approached at a perfect right-angle, it takes many small steps to reach the optimum. The more sophisticated conjugate gradient (CG) methods\cite{8} determine the new direction based not solely on the current gradient but on old gradients as well. This leads to a much better search behavior.

Inclusion of the second derivative (the Hessian matrix) is often used in curve-fit problems, or nonlinear least-squares routines. The quantity that is minimized must follow a $\chi^2$ distribution, which is often the case with errors from a fit. Calculation of the Hessian is possible precisely because of the assumption of the $\chi^2$ distribution. The standard method, which combines steepest descent and Hessian approaches, is the Marquardt–Levenberg method,\cite{8} using the former far from the optimum and the latter in the neighborhood of the optimum.

2.2 Response Surface Methods

Response surface methods stem from the area of experimental design,\cite{4,9} where in as few experiments as possible the maximum amount of information is extracted from a system. It is assumed that the response surface can be parameterized by a simple function with one optimum. The aim is to estimate the response function surface by choosing the experimental conditions intelligently. An often-used set-up is central composite design (CCD) depicted in Figure 6(a). Four points, arranged in a square, are combined with five points in the form of a star. In cases where the response is subject to error, one or more points (often the central point) may be replicated to obtain an estimate of the standard deviation. The fitted surface, using all terms to second degree, is given by Equation (1):

$$z = 433.7 - 0.061x - 0.371y - 1.1210^{-5}x^2 - 3.8810^{-6}y^2 + 9.4010^{-5}xy$$

(1)

where $z$ is the error, $x$ is $A$ and $y$ is $B$. The resulting surface is depicted in Figure 6(b).

This figure also clearly demonstrates the danger of extrapolating. According to the model, the optimal values are to be found in the upper left or lower right corners. One should only use these designs in the neighborhood of an optimum where one can be reasonably sure that the surface behaves as expected. Even very close to the global optimum this may not be the case.
2.3 Simplex Methods

Repeated application of small experimental designs can lead to the accurate and precise estimate of the optimum. Although sampling points can be reused, significantly decreasing the experimental effort, most response surface methods become impractical in spaces with more than three or four dimensions.

A simple extension that is more practical in spaces of moderate dimension is the simplex method. Instead of picking points in the search space according to an experimental design, one starts with the smallest number of experiments defining a surface in space; for example, for a two-dimensional space three points are chosen or, for a three-dimensional space, four points are chosen. This set of experiments, or points, is called the initial simplex. Next, one iterates by repeatedly selecting the worst point of the simplex and replacing it with a new point, obtained by mirroring the worst point in the side defined by the remaining points.

In two dimensions, this yields a series of adjoining triangles, as depicted in Figure 7(a), where the simplex method is applied to the error surface of Figure 3. The simplex is able to locate the global optimum approximately. The size of the simplex remains constant. This prohibits the method from finding an optimum with a better accuracy, and leads to an inefficient search behavior in smooth and monotonous error surfaces. An extension is the so-called modified simplex method, where the size of the simplex can be increased for more rapid convergence, or decreased for a more precise search. The results of this method are depicted in Figure 7(b). However, the optimum is found much more precisely, and in several cases the method is able to take big steps in the right direction, thus speeding up the optimization considerably.

In conclusion, the simplex method (and especially the modified simplex method) is an attractive optimization method in problems where experimentation is difficult or expensive, and where a number of other constraints are satisfied. The most important of these is the requirement that there is only one optimum, because otherwise
the simplex method may easily get stuck in a local optimum. This also implies that there should not be too much noise on the response variable, because this may lead to a projection of the wrong simplex vertex. In some cases this merely decreases the efficiency of the algorithm, in other cases it leads to completely wrong answers.\(^\text{12}\)

Although a number of experiments are performed, the results cannot readily be used to calculated response surfaces, because the experiments may be concentrated in one area of the search space. However, response-surface methods explicitly cover the relevant space. Simplex methods are very useful if improvement rather than an optimal solution is sought.

3 WEAK METHODS

Weak methods make almost no assumptions, but at a certain cost. In many cases they are not very effective, and they should only be used in very specific circumstances. The ultimate weak technique, evaluating all possible solutions, is practically infeasible for all but the most simple problems. Therefore, weak techniques sample the solution space in order to locate areas of good solutions. A strong random component is used in either selecting the sampling locations or defining the orientation of a group of samples. Repeated application of these methods may lead to quite different results, so the reproducibility of these searches is low.

3.1 Random Search

Random search is not a strategy many people would use, unless there is no other alternative. Yet in some molecular mechanics software packages it is implemented to serve as a reference point for other optimization procedures. The strategy is simple: just keep on trying new candidate solutions and keep the best one(s) until the time is up. The only situation in which this strategy is expected to be not worse than other methods is for "needle-in-a-haystack" problems – the landscape is completely flat and does not give any indication that one is near the optimum until the optimum is actually found. In such cases an exhaustive search is the only method guaranteed to find a solution, but is often not feasible. A typical example is molecular recognition – seemingly small changes to an active molecule can lead to a drastic decrease in activity. It is therefore not surprising that, especially in combinatorial chemistry, the random search strategy has led to the discovery of several interesting and completely new drug leads, although also in this field more sophisticated techniques are being investigated.

3.2 Sampling Methods

A more systematic way of sampling a landscape is to use a grid of a predefined size. Additional grids with smaller spacings may be placed in promising areas. An example of this is depicted in Figure 8(a), where the grid of 16 points used in the gradient search is followed by two other sampling steps. A disadvantage of this method is that phenomena smaller than the grid spacing are easily overlooked. Moreover, in search spaces with more dimensions the number of samples required increases drastically. In some well-understood problems of low dimension, however, this method can be used very well. The main advantage is its versatility – no attempt is made to parameterize the response surface and, if more than one optimum is found, several grids can be evaluated in parallel.

Figure 8 (a) Grid sampling and (b) stratified sampling. The spacing in the grids is 100, 25, and 7 units, respectively. The strata sizes are 100 × 100 and 25 × 25 units.
The stratified random search combines grid search with random search, by dividing the search space into strata and taking a random sample from each stratum. The problem that phenomena with a size smaller than the grid spacing may be overlooked is somewhat less acute in this approach. However, especially with large strata, some samples may be very close to each other leaving large parts of the search space empty. The number of samples per stratum may be increased if this is a problem. Again, a sequential approach may be used in which larger strata are followed by smaller ones. An example is indicated in Figure 8(b). There, the square in the original grid with the best sample value is further subdivided into smaller strata. Alternatively, a new set of strata can be centered at the location of the best sample.

Although sampling methods are grouped with the class of weak optimization methods, for a repeated application with decreasing intersample distance one must assume a more or less continuous form of response surface. This is not a very demanding assumption, however. The main problem with sampling approaches is the chance of missing important optima with a basin of attraction smaller than the intersample distance. In more than two or three dimensions this will frequently occur, because the number of sampling points must be kept manageable.

4 INTERMEDIATE METHODS

Stochastic optimization methods have been developed to counter the weaknesses of classical optimization methods in high-dimensional search problems. Instead of following a fixed path that is only determined by the choice of the starting point, they feature a strong random component, mainly to avoid getting trapped in local optima. Although finding the optimal solution is not guaranteed for all methods, in almost all cases these methods will find very good solutions. The most important methods are Monte Carlo simulated annealing (MCSA, or SA for short), GA and evolutionary strategies (ES), and tabu search (TS). The principles behind these methods are analogous to the physical cooling of a liquid (SA), Darwin’s theories of evolution (GA, ES) and learning processes (TS), respectively.

Although the roots of these methods lie in the 1960s, it was not until the mid-1980s (SA and GA) or later (TS) that these methods were applied in chemistry. The results clearly indicated that the methods offered solutions not achievable with the classical optimization methods.

4.1 Monte Carlo Simulated Annealing

MCSA, also known as the Metropolis algorithm, is probably the most used optimization method in chemistry today. Although the principle of the method was used in 1953 by Metropolis et al., it only became popular after 1983 when Kirkpatrick et al. described its use as a general optimization scheme. The method is implemented in a large number of software packages and is the de facto standard in structure optimization problems.

The principle of the method is very simple indeed. A random walk is performed in the search space, accepting all moves that lead to a better solution, and accepting moves that lead to a worse solution with a probability $e^{-\Delta E/T}$. This is analogous to the well-known Boltzmann distribution. If $T$, a control parameter often called the temperature is large, the chance of accepting a bad move is large as well and the search truly resembles a random walk. The search characteristics of SA are obtained by gradually lowering the temperature so that bad moves are more and more often rejected. It is clear that the cooling scheme is of prime importance for the success of the method. Indeed, proofs have been published guaranteeing convergence to the global optimum provided the cooling is done slowly enough. In practice, this proof is not very useful because adequate cooling may be infinitely slow. Many variants exist, including schemes that take into account the distance to the optimal evaluation function value (e.g. error = 0.0; this particular form of SA is called generalized simulated annealing (GSA)) or algorithms that use a Cauchy rather than a Boltzmann distribution.

The only parts that must be provided by the user are an evaluation function, a procedure to generate a new trial state and a cooling scheme. In particular the latter two have a profound influence on the performance of the algorithm and in some cases may be difficult to define. The algorithm is stopped when either the optimal solution has been found, a predefined number of evaluations is reached, or no improvement has been obtained for a specified number of evaluations.

A simple example using the error surface of Figure 3 is depicted in Figure 9(a). The SA is started from the center of the permissible region. A step consists of moving to one of the 24 closest points in the neighborhood. The temperature factor was set to 575 energy units at the beginning and gradually lowered to 525 units at the last of the 300 iterations. Nearly 40% of all proposed moves was accepted. As can be seen in the right plot in Figure 9(b), the algorithms wander around aimlessly for several periods of time, whereas in other periods rapid improvements are made.

Although in this case the SA finds the optimum without much trouble, in real problems a fair amount of fine tuning is usually necessary, especially in the move-generating and cooling procedures. Many practitioners use cooling schedules that keep the ratio of rejected versus accepted moves at around 1. Because of the stochastic
Figure 9 (a) SA to locate the optimum. Starting from the center of the admissible region, 300 iterations are performed. (b) The development of the error is depicted. Note the long period between iterations 80 and 260 where no improvement is made.

nature of SA, it is advisable to perform several runs from different starting points. There is no guarantee of finding the global optimum, especially in more difficult problems.

4.2 Tabu Search

Whereas SA performs an optimization by randomly generating a new state and applying the Boltzmann rule to decide whether to accept or reject, TS uses sophisticated history mechanisms to avoid evaluating solutions that are already known. In its simplest form, TS generates a new state by selecting the best available move, excluding those states that are members of the tabu list $T$. To prevent memory problems, however, a tabu list usually contains moves, or components of moves, instead of states. This list of tabu moves is continually updated and consists of those moves (or move components) that would undo the most recent iterations in the search process. The net effect of the tabu list is that cycles with a length smaller than the length of the tabu list are avoided.

The TS paradigm is made more sophisticated by inclusions of aspiration criteria. These play the opposite role of the tabu moves – a move is regarded as admissible if its aspiration criteria are satisfied. Examples include situations where a move would lead to a better solution than all previously visited solutions, or where a move (component) has not been executed for a long time. Furthermore, intermediate- and long-term memory functions are used to identify attribute values that are clearly important for good solutions, and to diversify the search, respectively. Thus, the search can be focused to particular regions in space or the algorithm can escape from local optima.

The separate components of TS methods are much more problem dependent than is usually the case with other optimization methods. However, they are intuitively appealing and with expert knowledge about the problem not too difficult to define. The number of applications in chemistry is still limited, mainly because the method has been used primarily for sequential problems. Recently, several applications have been reported on structure optimization problems, assessing chemical similarity, and molecular docking.

4.3 Evolutionary Optimization

A large number of different techniques fall under the header of evolutionary optimization, most notably evolutionary algorithms (EA) and GAs. Their main characteristic is that they use a population of trial solutions, instead of proceeding from one trial solution to the next. This may have several advantages. For example, in cases where one is interested not only in the global optimum but also in other good solutions, population-based methods may prevent the same optimum being found continuously. Thus, in principle, a more diverse set is found. Examples where this is very important are abundant – in chemistry, molecular structure optimization is used to find not only the global energy minimum but also all other structures that are feasible at room temperature.

The second important aspect of the use of a population is that there is no need to define how new solutions are obtained. In methods such as TS or SA one has to define how to proceed from the current solution to the next, but in EA this is typically performed by standard operators such as cross-over and mutation. Where the latter in most applications is a more or less random disruption of a member of the population, the former is specific for evolutionary optimization. In analogy with nature, two (or more) members of the population mate and exchange genetic material to produce children. The genetic material consists of parts of the solutions, and is coded either in binary form or as real numbers. Cross-over is also governed by chance, so no attempt is made
to identify “good” parts of a solution for reproduction. The best genetic material is more or less automatically preserved because solutions of a high quality will be selected for parenthood more often than bad solutions. The “genes” of the latter will gradually be removed from the population as the evolution goes on for a number of generations.

The success of EAs depends on the combination of representation and evolutionary operators. In general, evolutionary operators that yield invalid solutions (such as parameter values outside a permissible range, or impossible chemical structures in a structure-manipulation application) are to be avoided. Many applications have been described in molecular structure optimization, spectrum interpretation, subset selection for QSAR, and multivariate calibration and other fields."\(^{21,22}\)

### 4.4 Hybrid Methods

Hybrid methods combine the characteristics of different optimization methods. Typically, the basic optimization cycle of Figure 1 is composed of elements from the individual methods. Of course, many methods differ only in one aspect. The main difference between TS and steepest descent methods, for example, is in the generation stage – some solutions are forbidden by the tabu list or explicitly allowed, but each method selects the best of the admissible moves. One further difference is that TS may accept a worse solution if that is the best one available, whereas steepest descent then stops.

Of course, hybrid methods are most useful when they combine the best features of their components. One approach which has been used in practice is a hybrid form of a GA and SA. The GA is used to maintain a pool of trial solutions and to generate offspring; the SA governs the selection part by accepting all improving solutions and accepting worse solutions according to the Boltzmann distribution. The advantages of the GA are that inadmissible regions of the search space are handled gracefully and do not constitute a barrier that a vintage SA may find difficult to cross. The advantage of the SA is the added control that the user may exert through the cooling scheme. For the selection and generation stages, typical strategies are summarized in Table 1. Other possible hybrids are GA/TS (a pool of solutions is maintained and the random reproduction mechanism is supervised by TS methods) and SA/TS (probabilistic TS, where the chance of accepting a new solution is governed by the SA Boltzmann distribution).

The main strengths of all these methods – their versatility and their ability to adapt to all kinds of problems – are also their weakness. No generally accepted strategies for selecting, adapting and fine tuning these global search methods exist. If one is lucky, the methods work straight away. However, one may not be lucky, and although there are a million ways to alter and tweak the algorithms, no guidelines exist as to which one is best. Fortunately, in many cases suitable starting points and standard settings can be found in the literature for analogous problems.

### 4.5 Comparison of Methods

The question as to which of the intermediate methods mentioned so far is most suited for a particular problem is not easily answered, for several reasons. Although they are often called “global” optimization methods, in many practical problems there is no guarantee that the true global optimum will be found. Replicate runs may find radically different solutions, either because of the stochastic nature of the search performed (all but TS) or because of the influence of the starting position (all methods). This means that for a thorough comparison many replicate runs should be performed on a representative set of example problems. As these problems usually take a fair amount of computing time, extensive comparisons between algorithms are rarely performed.

A second problem is that each algorithm comes in many variants, each with a set of optimization parameters that can be fine tuned. This tuning may be critical to the performance of the algorithm and constitutes a meta-optimization problem. It is also difficult to give each of the algorithms tested the same level of attention – often, one of the techniques is already known to the implementors and this may give it a decisive advantage.

Finally, there is no clear-cut criterion with which to judge the performance of the optimization methods. Simply looking at the quality of the best solution clearly does not provide all the information. Therefore, other criteria are needed."\(^{17,23}\) If these are not explicitly based

on the value of the evaluation function, the form of this function can be tuned as well. For a successful application of these intermediate search methods, the ensemble of representation, the search operations, and the evaluation function must be adjusted to each other.

5 CONCLUSIONS AND OUTLOOK

The field of optimization is broad and has applications in all areas of chemistry. Naturally, many different methods have been used and in some cases even developed by chemists. In this article, an overview is given where the methods have been classified as “classical” or “nonclassical”. The former category comprises methods that are very good in dealing with low-dimensional problems. An example is the optimization of a chromatographic experiment, where optimal separation conditions should be found in as few experiments as possible. These methods are said to be strong because they incorporate much knowledge from the user about the problem at hand. The classical category also embraces weak methods where knowledge is not a prerequisite. As the efficiency of these methods is in many cases very low, they are not often used in chemistry.

The nonclassical optimization techniques described in this article have been specifically developed for those cases where the classical techniques were not suitable – high-dimensional search problems with many local optima. Because the number of evaluations may be quite high they usually are applied in connection with computer experiments rather than with laboratory experiments. A notable exception is found in the field of combinatorial chemistry, where GAs have been used to guide the synthesis of new promising lead molecules.\(^{24}\)

The classical and nonclassical methods have complementary roles in chemistry. With the increasing role of computational chemistry, the nonclassical methods will continue to flourish. However, due to their complicated nature and great versatility, they will remain the playground of experts in the near future. With classical methods the situation is different. Many standard computer software packages are available for experimental design, and are sometimes even included in laboratory instruments. Although the principles of the methods should still be understood by the user, no programming is required, thereby significantly lowering the threshold for their use.

Clustering and classification are the major subdivisions of pattern recognition techniques. Using these techniques, samples can be classified according to a specific property by measurements indirectly related to the property of interest (such as the type of fuel responsible for an underground spill). An empirical relationship or classification rule can be developed from a set of samples for which the property of interest and the measurements are known. The classification rule can then be used to predict the property in samples that are not part of the original training set. The classification rule can be developed from a set of samples for which the property of interest and the measurements are known. The set of samples for which the property of interest and measurements is known is called the training set. The set of measurements that describe each sample in the data set is called a pattern. The determination of the property of interest by assigning a sample to its respective category is called recognition, hence the term pattern recognition.

For pattern recognition analysis, each sample is represented as a data vector \( \mathbf{x} = (x_1, x_2, x_3, \ldots, x_n) \), where component \( x_j \) is a measurement, e.g. the area \( a \) of the \( j \)th peak in a chromatogram. Thus, each sample is considered as a point in an \( n \)-dimensional measurement space. The dimensionality of the space corresponds to the number of measurements that are available for each sample. A basic assumption is that the distance between pairs of points in this measurement space is inversely related to the degree of similarity between the corresponding samples. Points representing samples from one class will cluster in a limited region of the measurement space distant from the points corresponding to the other class. Pattern recognition (i.e. clustering and classification) is a set of methods for investigating data represented in this manner, in order to assess its overall structure, which is defined as the overall relationship of each sample to every other in the data set.

1 INTRODUCTION

Since the early 1980s, a major effort has been made to substantially improve the analytical methodology applied to the study of environmental samples. Instrumental techniques such as gas chromatography, high-performance liquid chromatography (HPLC) and X-ray fluorescence spectroscopy have dramatically increased the number of organic and inorganic compounds that can be identified and quantified, even at trace levels, in the environment. This capability, in turn, has allowed scientists to attack ever more complex problems, such as oil and fuel spill identification, but has also led to an information-handling problem.\(^1\)

The reason for this problem is that in any monitoring effort it is necessary to analyze a large number of samples in order to assess the wide variation in composition that an environmental system may possess. The large number of samples that must be analyzed and the number of constituents that must be measured per sample give rise to data sets of enormous size and complexity. Often, important relationships in these data sets cannot be uncovered, when the data are examined one variable at a time, because of correlations between measurement variables, which tend to dominate the data and prevent information from being extracted.

Furthermore, the relationships sought in the data often cannot be expressed in quantitative terms, such as the source of a pollutant in the environment. These relationships are better expressed in terms of similarity or dissimilarity among groups of multivariate data. The task that confronts the scientist when investigating these sorts of relationships in multivariate data, is twofold:

- Can a useful structure based on distinct sample groups be discerned?
- Can a sample be classified into one of these groups for the prediction of some property?

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
The first question is addressed using principal component analysis (PCA)\(^2\) or cluster analysis\(^3\) whereas the second question is addressed using pattern recognition methods\(^4\).

PCA is the most widely used multivariate analysis technique in science and engineering\(^5\). It is a method for transforming the original measurement variables into new variables called principal components. Each principal component is a linear combination of the original measurement variables. Often, only two or three principal components are necessary to explain all of the information present in the data. By plotting the data in a coordinate system defined by the two or three largest principal components, it is possible to identify key relationships in the data, that is, find similarities and differences among objects (such as chromatograms or spectra) in a data set.

Cluster analysis\(^6\) is the name given to a set of techniques that seek to determine the structural characteristics of a data set by dividing the data into groups, clusters, or hierarchies. Samples within the same group are more similar to each other than samples in different groups. Cluster analysis is an exploratory data analysis procedure. Hence, it is usually applied to data sets for which there is no a priori knowledge concerning the class membership of the samples.

Pattern recognition\(^7\) is a name given to a set of techniques developed to solve the class-membership problem. In a typical pattern recognition study, samples are classified according to a specific property using measurements that are indirectly related to that property. An empirical relationship or classification rule is developed from a set of samples for which the property of interest and the measurements are known. The classification rule is then used to predict this property in samples that are not part of the original training set. The property in question may be the type of fuel responsible for a spill, and the measurements are the areas of selected gas chromatographic (GC) peaks. Classification is synonymous with pattern recognition, and scientists have turned to it and PCA and cluster analysis to analyze the large data sets typically generated in monitoring studies that employ computerized instrumentation.

This article explores the techniques of PCA, cluster analysis, and classification. The procedures that must be implemented to apply these techniques to real problems are also enumerated. Special emphasis is placed on the application of these techniques to problems in environmental analysis.

### 2 PRINCIPAL COMPONENT ANALYSIS

PCA is probably the oldest and best known of the techniques used for multivariate analysis. The overall goal of PCA is to reduce the dimensionality of a data set, while simultaneously retaining the information present in the data. Dimensionality reduction or data compression is possible with PCA because chemical data sets are often redundant. That is, chemical data sets are not information rich. Consider a gas chromatogram of a JP-4 fuel (Figure 1), which is a mixture of alkanes, alkenes, and aromatics. The gas chromatogram of a JP-4 fuel is characterized by a large number of early-eluting peaks, which are large in size. There are a few late-eluting peaks, but their size is small. Clearly, there is a strong negative correlation between the early- and late-eluting peaks of the JP-4 fuel. Furthermore, many of the alkane and alkene peaks are correlated, which should not come as a surprise as alkenes are not constituents of crude oil but instead are formed from alkanes during the refining process. In addition, the property of a fuel most likely to be reflected in a high resolution gas chromatogram is its distillation curve, which does not require all 85 peaks for characterization.

![Figure 1](image)

**Figure 1** A high-resolution capillary column gas chromatogram of a JP-4 fuel.

![Figure 2](image)

**Figure 2** Seventeen hypothetical samples projected onto a two-dimensional measurement space defined by the measurement variables \(X_1\) and \(X_2\). The vertices, A, B, C, and D, of the rectangle represent the smallest and largest values of \(X_1\) and \(X_2\). (Adapted from Mandel.\(^8\))
Redundancy in data is due to collinearity (i.e. correlations) among the measurement variables. Collinearity diminishes the information content of the data. Consider a set of samples characterized by two measurements, \( X_1 \) and \( X_2 \). Figure 2 shows a plot of these data in a two-dimensional measurement space, where the coordinate axes (or basis vectors) of this measurement space are the variables \( X_1 \) and \( X_2 \). There appears to be a relationship between these two measurement variables, which suggests that \( X_1 \) and \( X_2 \) are correlated, because fixing the value of \( X_1 \) limits the range of values possible for \( X_2 \). If the two measurement variables were uncorrelated, the enclosed rectangle in Figure 2 would be fully populated by the data points. Because information is defined as the scatter of points in a measurement space, it is evident that correlations between the measurement variables decrease the information content of this space. The data points, which are restricted to a small region of the measurement space due to correlations among the variables, could even reside in a subspace if the measurement variables are highly correlated. This is shown in Figure 3. Here \( X_3 \) is perfectly correlated with \( X_1 \) and \( X_2 \) because \( X_1 \) plus \( X_2 \) equals \( X_3 \). Hence, the seven sample points lie in a plane even though each data point has three measurements associated with it.

### 2.1 Variance-based Coordinate System

Variables that have a great deal of redundancy or are highly correlated are said to be collinear. High collinearity between variables is a strong indication that a new set of basis vectors can be found that will be better at conveying the information content present in data than axes defined by the original measurement variables. The new basis set that is linked to variation in the data can be used to develop a new coordinate system for displaying the data. The principal components of the data define the variance-based axes of this new coordinate system.

![Figure 4](image)

**Figure 4** Principal component axes developed from the measurement variables \( r \), \( c \), and \( t \). (Reproduced by permission from Brown\(^5\) courtesy of Society of Applied Spectroscopy.)

The largest or first principal component is formed by determining the direction of largest variation in the original measurement space and modeling it with a line fitted by linear least squares (Figure 4) that passes through the center of the data. The second largest principal component lies in the direction of next largest variation – it passes through the center of the data and is orthogonal to the first principal component. The third largest principal component lies in the direction of next largest variation – it also passes through the center of the data, it is orthogonal to the first and second principal components, and so forth. Each principal component describes a different source of information because each defines a different direction of scatter or variance in the data. (The scatter of the data points in the measurement space is a direct measure of the data’s variance.) Hence, the orthogonality constraint imposed by the mathematics of PCA ensures that each variance-based axis will be independent.

### 2.2 Information Content of Principal Components

One measure of the amount of information conveyed by each principal component is the variance of the data explained by the principal component. The variance explained by each principal component is expressed in terms of its eigenvalue. For this reason, principal components are usually arranged in order of decreasing eigenvalues or waning information content. The most informative principal component is the first and the least informative is the last. The maximum number of
principal components that can be extracted from the data is the smaller of either the number of samples or number of measurements in the data set, as this number defines the largest number of independent variables in the data.

If the data are collected with due care, one would expect that only the first few principal components would convey information about the signal, as most of the information in the data should be about the effect or property of interest being studied. However, the situation is not always this straightforward. Each principal component describes some amount of signal and some amount of noise in the data because of accidental correlation between signal and noise. The larger principal components primarily describe signal variation, whereas the smaller principal components essentially describe noise. When smaller principal components are deleted, noise is being discarded from the data, but so is a small amount of signal. However, the reduction in noise more than compensates for the biased representation of the signal that results from discarding principal components that contain a small amount of signal but a large amount of noise. Plotting the data in a coordinate system defined by the two or three largest principal components often provides more than enough information about the overall structure of the data. This approach to describing a data set in terms of important and unimportant variation is known as soft modeling in latent variables.

PCA takes advantage of the fact that a large amount of data is usually generated in monitoring studies when sophisticated chemical instrumentation, which is commonly under computer control, is used. The data have a great deal of redundancy and therefore a great deal of collinearity. Because the measurement variables are correlated, 85 peak gas chromatograms do not necessarily require 85 independent axes to define the position of the sample points. Utilizing PCA, the original measurement variables that constitute a correlated axis system can be converted into a system that removes correlation by forcing the new axes to be independent and orthogonal. This requirement greatly simplifies the data because the correlations present in the data often allow us to use fewer axes to describe the sample points. Hence, the gas chromatograms of a set of JP-4 and Jet-A fuel samples may reside in a subspace of the 85-dimensional measurement space. A plot of the two or three largest principal components of the data can help us to visualize the relative position of the Jet-A and JP-4 fuel samples in this subspace.

2.3 Case Studies

With PCA, we are able to plot the data in a new coordinate system based on variance. The origin of the new coordinate system is the center of the data, and the coordinate axes of the new system are the principal components of the data. Employing this new coordinate system, we can uncover relationships present in the data, that is, find distinct samples subgroups within the data. This section shows, by way of two published studies, how principal components can be used to discern similarities and differences among sample within a data set.

2.3.1 Troodos Data Set

In the first study, 143 rock samples collected in the Troodos region of Cyprus were analyzed by X-ray fluorescence spectroscopy for 10 metal oxides, which contained information about the formation of these rocks. If the formation of the entire Troodos region occurred at the same time, one would expect all of the rocks to be similar in composition. However, if there are distinct subgroups in the data, other conclusions may have to be drawn about the formation of the Troodos region. This study was initiated to settle a controversy about the geological history of Cyprus.

Figure 5 shows a plot of the two largest principal components of the 143 rock samples. (The original Troodos data set was modified for the purpose of this principal component mapping exercise.) Samples 65 and 66 appear to be outliers in the plot as they are distant from the other samples. As a general rule, outliers should deleted because of the least-squares property of principal components. In other words, a sample that is distant from the other points in the measurement space can pull the principal components towards it and away from the direction of maximum variance. Figure 6 shows the results of a principal component mapping experiment.

![Figure 5](image_url) A principal component map of the 143 rock samples. Samples 65 and 66 are outliers. (The original data set was modified for this principal component mapping exercise.) The principal component map was generated using the program UNSCRAMBLER.
Figure 6 A principal component map of the Troodos rock samples with samples 65 and 66 removed. Samples 129 and 130 appear as outliers in the plot. (The original data set was modified for this principal component mapping exercise.) The principal component map was generated using the program UNSCRAMBLER.

Figure 7 A principal component map of the Troodos rock samples with samples 65, 66, 129, and 130 removed. The principal component map was generated using the program UNSCRAMBLER.

with samples 65 and 66 removed from the data. It is evident from the plot that samples 129 and 130 are also outliers. Figure 7 summarizes the results of a principal component mapping experiment with samples 65, 66, 129, and 130 removed. Although samples 19 and 20 are probably outliers and are also candidates for removal, it is evident from the principal component plot that the rock samples can be divided into two groups, which would suggest that other conclusions should be drawn about the geological history of the Troodos region. The clustering of the rocks samples into two distinct groups was not apparent until the four outliers were removed from the data.

Figure 8 A plot of the two largest principal components for the 63 Indian artifacts developed from the concentration data of 10 metals. The principal component map was generated using the program SCAN.

2.3.2 Obsidian Data Set

The second study also involves X-ray fluorescence data. Sixty-three Indian artifacts (such as jewelry, weapons, and tools) made from volcanic glass, were collected from four quarries in the San Francisco Bay area. (Samples 1–10 are from quarry 1, samples 11–19 are from quarry 2, samples 20–42 are from quarry 3, and samples 43–63 are from quarry 4.) Because the composition of volcanic glass is characteristic of the site and tends to be homogeneous, it is reasonable to assume that it should be possible to trace these artifacts to their original source material. In this study, the investigators attempted to do this by analyzing the 63 glass samples for 10 elements: Fe, Ti, Ba, Ca, K, Mn, Rb, Sr, Y, and Zn. Next, a PCA was performed on the data (63 artifacts with 10 features per artifact). The goal was to identify the overall trends present in the data. Figure 8 shows a plot of the two largest principal components of the data. From the principal component map, it is evident that the 63 Indian artifacts can be divided into four groups, which correspond to the quarry sites from which the artifacts were collected. Evidently, the artifacts in each quarry were made from the same source material. This result is significant because it provides the archaeologists with important information about the migration patterns and trading routes of the Indians in this region. Further details about the obsidian data can be found elsewhere.

3 CLUSTER ANALYSIS

Cluster analysis is a popular technique whose basic objective is to discover sample groupings within data. The technique is encountered in many fields, such as biology, geology, and geochemistry, under such
names as unsupervised pattern recognition and numerical taxonomy. Clustering methods are divided into three categories, hierarchical, object-functional, and graph theoretical. The focus here is on hierarchical methods, as they are the most popular.

For cluster analysis, each sample is treated as a point in an n-dimensional measurement space. The coordinate axes of this space are defined by the measurements used to characterize the samples. Cluster analysis assesses the similarity between samples by measuring the distances between the points in the measurement space. Samples that are similar will lie close to one another, whereas dissimilar samples are distant from each other. The choice of the distance metric to express similarity between samples in a data set depends on the type of measurement variables used.

Typically, three types of variables – categorical, ordinal, and continuous – are used to characterize chemical samples. Categorical variables denote the assignment of a sample to a specific category. Each category is represented by a number, such as 1, 2, 3, etc. Ordinal variables are categorical variables, in which the categories follow a logical progression or order, such as low, middle, and high, respectively. However, continuous variables are quantitative. The difference between two values for a continuous variable has a precise meaning. If a continuous variable assumes the values 1, 2, and 3, the difference between the values 3 and 2 will have the same meaning as the difference between the values 2 and 1, because they are equal.

Measurement variables are usually continuous. For continuous variables, the Euclidean distance is the best choice for the distance metric, because interpoint distances between the samples can be computed directly (Figure 9). However, there is a problem with using the Euclidean distance, which is the so-called scaling effect. It arises from inadvertent weighting of the variables in the analysis that can occur due to differences in magnitude among the measurement variables. For example, consider a data set where each sample is described by two variables: the concentration of Na and the concentration of K as measured by atomic flame emission spectroscopy. The concentration of Na varies from 50 to 500 ppm, whereas the concentration of K in the same samples varies from 5 to 50 ppm. A 10% change in the Na concentration will have a greater effect on Euclidean distance than a 10% change in K concentration. The influence of variable scaling on the Euclidean distance can be mitigated by autoscaling the data, which involves standardizing the measurement variables, so that each variable has a mean of zero and a standard deviation of 1 (Equation 1):

\[ x_{i,\text{standardized}} = \frac{x_{i,\text{orig}} - m_{i,\text{orig}}}{s_{i,\text{orig}}} \]

where \( x_{i,\text{orig}} \) is the original measurement variable \( i \), \( m_{i,\text{orig}} \) is the mean of the original measurement variable \( i \), and \( s_{i,\text{orig}} \) is the standard deviation of the original measurement variable \( i \). Thus, a 10% change in K concentration has the same effect on the Euclidean distance as a 10% change in Na concentration when the data is autoscaled. Clearly, autoscaling ensures that each measurement variable has an equal weight in the analysis. For cluster analysis, it is best to autoscale the data, because similarity is directly determined by a majority vote of the measurement variables.

3.1 Hierarchical Clustering

Clustering methods attempt to find clusters of patterns (i.e. data points) in the measurement space, hence the term cluster analysis. Although several clustering algorithms exist, e.g. K-means, K-mediant, Patrick-Jarvis, FCV (fuzzy clustering varieties), hierarchical clustering is by far the most widely used clustering method. The starting point for a hierarchical clustering experiment is the similarity matrix which is formed by first computing the distances between all pairs of points in the data set. Each distance is then converted into a similarity value (Equation 2):

\[ s_{ik} = 1 - \frac{d_{ik}}{d_{\text{max}}} \]

where \( s_{ik} \) (which varies from 0 to 1) is the similarity between samples \( i \) and \( k \), \( d_{ik} \) is the Euclidean distance between samples \( i \) and \( k \), and \( d_{\text{max}} \) is the distance between the two most dissimilar samples (i.e. the largest distance) in the data set. The similarity values are organized in the form of a table or matrix. The similarity matrix is
then scanned for the largest value, which corresponds to
the most similar point pair. The two samples constituting
the point pair are combined to form a new point, which
is located midway between the two original points. The
rows and columns corresponding to the old data points
are then removed from the matrix. The similarity matrix
for the data set is then recomputed. In other words,
the matrix is updated to include information about the
similarity between the new point and every other point in
the data set. The new nearest point pair is identified, and
combined to form a single point. This process is repeated
until all points have been linked.

There are a variety of ways to compute the distances
between data points and clusters in hierarchical clustering
(Figure 10). The single-linkage method assesses similarity
between a point and a cluster of points by measuring
the distance to the closest point in the cluster. The
complete linkage method assesses similarity by measuring
the distance to the farthest point in the cluster. Average
linkage assesses the similarity by computing the distances
between all point pairs where a member of each pair
belongs to the cluster. The average of these distances is
used to compute the similarity between the data point
and the cluster.

To illustrate hierarchical clustering, consider the data
shown in Table 1. (The example shown here is an
adaptation of the exercise described in Chapter 6 of
reference 4.) Five HPLC columns were characterized by
the capacity factor values obtained from three substances,
which served as retention probes. To perform single-
linkage hierarchical clustering on this chromatographic
data, it is necessary to first compute the similarity matrix
for the data, given as Table 2.

The similarity matrix (Table 2) is then scanned for
the largest value, which corresponds to the two HPLC
columns that are most similar. An examination of
the similarity matrix suggests that chromatographic
columns A and B with a score of 0.79 are the most
similar. Hence, chromatographic columns A and B should
be combined to form a new point. The rows and columns
corresponding to the two original points (A and B) are
removed from the similarity matrix. The similarity matrix
for the data set is then updated to include information
about the similarity between the new point and every other point in
the data set. The new nearest point pair is identified, and
combined to form a single point. This process is repeated
until all points have been linked.

and 0.17, see Table 2. For complete linkage, the similarity between this cluster and point D is the smaller of the two values.)

The updated similarity matrix is then scanned for the largest value; the new nearest pair is combined to form a single point, which is points D and E. The rows and columns corresponding to points D and E are deleted from the similarity matrix. The similarity matrix for the data set is then updated (Table 4) to include information about the similarity between the new point (D + E) and every other point in the data set. This process is repeated (Table 5) until all points are merged into a single cluster.

The results of a hierarchical clustering study are usually displayed as a dendogram, which is a tree-shaped map of the intersample distances in the data set. The dendogram shows the merging of samples into clusters at various stages of the analysis and the similarities at which the clusters merge, with the clustering displayed hierarchically. The dendogram for the single-linkage analysis of the HPLC data is shown in Figure 11. Interpretation of the results is intuitive, which is the major reason for the popularity of these methods.

### 3.2 Practical Considerations

A major problem in hierarchical clustering (or cluster analysis for that matter) is defining a cluster. Contrary to many published reports, there is no cluster validity measure that can serve as an indicator of the quality of a proposed partitioning of the data. Hence, clusters are defined intuitively, depending on the context of the problem, not mathematically, which limits the utility of this technique. Clearly, prior knowledge about the problem is essential when using these methods. The criterion for determining the threshold value for similarity is often subjective and depends to a large degree on the nature of the problem investigated – for example, the goals of the study, the number of clusters sought, previous experience, and common sense.

All clustering procedures yield the same results for data sets with well-separated clusters. However, the results will differ when the clusters overlap. That is why it is a good idea to use at least two different clustering algorithms, such as single and complete linkage, when studying a data set. If the dendograms are in agreement, then a strong case can be made for partitioning the data into distinct groups as suggested by the dendograms. If the cluster memberships differ, the data should be further investigated using average linkage or PCA. The results from average linkage or PCA can be used to gauge whether the single or farthest linkage solution is the better one.

All hierarchical clustering techniques suffer from so-called space distorting effects. For example, single-linkage favors the formation of large linear clusters instead of the usual elliptical or spherical clusters. As a result, poorly separated clusters are often chained together. However, complete linkage favors the formation of small spherical clusters. Because of these space-distorting effects, hierarchical clustering methods should be used in tandem with PCA to detect clusters in multivariate data sets.

All hierarchical methods will always partition data, even randomly generated data, into distinct groups or clusters. Hence, it is important to ascertain the significance level of the similarity value selected by the user. For this task, a simple three-step procedure is proposed. First, a random data set is generated with the same correlation structure, the same number of samples, and the same number of measurements as the real data set that is currently being investigated. Second, the same clustering technique(s) is applied to the random data. Third, the similarity value, which generates the same number of clusters as identified in the real data set, is determined from the dendogram of the random data. If the similarity value is substantially larger for the real data set, the likelihood of having inadvertently exploited random variation in the data to achieve clustering is probably insignificant.

### 3.3 Case Studies

Hierarchical clustering methods attempt to uncover the intrinsic structure of a multivariate data set without making a priori assumptions about the data. This section,
Figure 12 A single-linkage dendogram of the obsidian data set. The dendogram was generated using the program SCAN.

shows, by way of two published studies, how clustering methods can be used to find clusters of points in data.

3.3.1 Obsidian Data Set

The first study is the obsidian data set, discussed in section 2.3.2. A principal component map of the data (Figure 8) revealed four distinct clusters, which correspond to the sites from which these artifacts were obtained. To confirm the four-cluster hypothesis, the investigators also analyzed their data using single-linkage analysis. The resulting dendogram (Figure 12) indicated that it is reasonable to divide the glass samples into four categories based on the quarry sites from which these artifacts were obtained. (At similarity 0.40, samples 1–10 form a cluster, samples 11–19 form another cluster, samples 20–42 form a third cluster, and samples 43–63 form the fourth cluster.) Because the dendogram and principal component map of the data are in strong agreement, the investigators decided to partition their data into four groups based on the quarry labels of the samples.

3.3.2 Artificial Nose Data Set

The second study involves data from an artificial nose. (A salesman claims that an electronic nose can successfully sniff odor. The salesman obtained data from the literature to support his claim. Of the 41 compounds in the data set, compounds 1–21 are ethereal, compounds 22–32 are pungent, and compounds 33–41 are minty. Each compound was characterized by six electronic measurements. Using a back-propagation neural network algorithm, the salesman was able to correctly classify all of the compounds in the data set. Should we then accept the salesman’s claim that an electronic nose can sniff odor?

In order to validate the salesman’s claim, the odor data was analyzed using single and complete linkage hierarchical clustering. Figures 13 and 14 show dendograms of the odor data. It is evident from the dendograms that dividing the 41 compounds into three categories based on odor type cannot be justified. (Although the data can be divided into three clusters by complete linkage at a 0.56 similarity, the cluster memberships cannot be correlated to compound odor – why? Cluster 1 consists of samples 41, 21, 19, 16, 13, 39, 31, 36, 29, 8, 34, and 32. Cluster 2 consists of samples 38, 5, 26, 14, 24, 15, 37, 6, 33, 35, 20, 30, and 7. Cluster 3 consists of samples 40, 17, 4, 22, 2, 25, 10, 28, 18, 27, 23, 12, 11, 1, 9, and 3.) Evidently, the six electronic measurements from the nose do not contain sufficient discriminatory information to force the compounds to cluster on the basis of odor type. Therefore, the salesman’s claim about the efficacy of the proposed artificial nose should not be accepted at face value.

4 PATTERN RECOGNITION

So far, only exploratory data analysis techniques, i.e. cluster analysis and PCA, have been discussed. These techniques attempt to analyze data without directly using information about the class assignment of the samples. Although cluster analysis and PCA are powerful methods for uncovering relationships in large multivariate data sets, they are not sufficient for developing a classification rule that can accurately predict the class-membership of
an unknown sample. In this section, pattern recognition techniques will be discussed. These techniques were originally developed to categorize a sample on the basis of regularities in observed data. The first applications of pattern recognition to chemistry were studies involving low-resolution mass spectrometry.\textsuperscript{(12)} Since then, pattern recognition techniques have been applied to a wide variety of chemical problems, such as chromatographic fingerprinting,\textsuperscript{(13–15)} spectroscopic imaging,\textsuperscript{(16–18)} and data interpretation.\textsuperscript{(19–21)}

Pattern recognition techniques fall into one of two categories: nonparametric discriminants, and similarity-based classifiers. Nonparametric discriminants,\textsuperscript{(22–24)} such as neural networks, attempt to divide a data space into different regions. In the simplest case, that of a binary classifier, the data space is divided into two regions.
Samples that share a common property (such as fuel type) will be found on one side of the decision surface, whereas those samples comprising the other category will be found on the other side. Nonparametric discriminants have provided insight into relationships contained within sets of chemical measurements. However, classification based on random or chance separation can be a serious problem if the data set is not sample rich. Because chemical data sets usually contain more variables than samples, similarity-based classifiers are generally preferred.

Similarity-based classifiers, e.g. k-nearest neighbor (KNN) and soft independent modeling by class analogy (SIMCA), treat each chromatogram or spectrum as a data vector \( \mathbf{x} = (x_1, x_2, \ldots, x_j, \ldots, x_p) \) where component \( x_j \) is the area of the \( j \)th peak or the absorbance value of the \( j \)th wavelength. Such a vector can also be viewed as a point in a high-dimensional measurement space. A basic assumption is that distances between points in the measurement space will be inversely related to their degree of similarity.

Figure 14 A complete-linkage dendogram of the nose data set. The dendogram was generated using the program Pirouette.
Using a similarity-based classifier we can determine the class-membership of a sample by examining the class label of the data point closest to it or from the principal component model of the class, which lies closest to the sample in the measurement space. In chemistry, similarity-based classification rules are implemented using either KNN or SIMCA.

4.1 k-Nearest Neighbor

For its simplicity, KNN is a powerful classification technique. A sample is classified according to the majority vote of its KNNs, where \( k \) is an odd integer (one, three, or five). For a given sample, Euclidean distances are first computed from the sample to every other point in the data set. These distances arranged from smallest to the largest are used to define the sample’s KNNs. A poll is then taken by examining the class identities among the point’s KNNs. Based on the class identity of the majority of its KNNs, the sample is assigned to a class in the data set. If the assigned class and the actual class of the sample match, the test is considered a success. The overall classification success rate, calculated over the entire set of points, is a measure of the degree of clustering in the set of data. Clearly, a majority vote of the KNNs can only occur if the majority of the measurement variables concur, because the data is usually autoscaled.

KNN cannot furnish a statement about the reliability of a classification. However, its classification risk is bounded. In other words, the Bayes classifier will generate the optimal classification rule for the data, and 1-nearest neighbor has an error rate which is twice as large as the Bayes classifier. (To implement the Bayes classifier, one must have knowledge about all the statistics of the data set including the underlying probability distribution function for each class. Usually, this knowledge is not available.) Hence, any other classification method, no matter how sophisticated, can at best only improve on the performance of KNN by a factor of two.

4.2 Soft Independent Modeling by Class Analogy

In recent years, modeling approaches have become popular in analytical chemistry for developing classification rules because of the problems with nonparametric discriminants. Although there are a number of approaches to modeling classes, the SIMCA method, based on PCA, has been developed by Wold for isolating groups of multivariate data or classes in a data set. In SIMCA, a PCA is performed on each class in the data set, and a sufficient number of principal components are retained to account for most of the variation within each class. Hence, a principal component model is used to represent each class in the data set. The number of principal components retained for each class is usually different. Deciding on the number of principal components that should be retained for each class is important, as retention of too few components can distort the signal or information content contained in the model about the class, whereas retention of too many principal components diminishes the signal-to-noise. A procedure called cross-validation ensures that the model size can be determined directly from the data. To perform cross-validation, segments of the data are omitted during the PCA. Using one, two, three, etc., principal components, omitted data are predicted and compared to the actual values. This procedure is repeated until every data element has been kept out once. The principal component model that yields the minimum prediction error for the omitted data is retained. Hence, cross-validation can be used to find the number of principal components necessary to describe the signal in the data while ensuring high signal-to-noise by not including the so-called secondary or noise-laden principal components in the class model.

The variance that is explained by the class model is called the modeled variance, which describes the signal, whereas the noise in the data is described by the residual variance or the variance not accounted for by the model. (The residual variance is explained by the secondary principal components, which have been truncated or omitted from the principal component model.) By comparing the residual variance of an unknown to the average residual variance of those samples that make up the class, it is possible to obtain a direct measure of the similarity of the unknown to the class. This comparison is also a measure of the goodness of fit of the sample to a particular principal component model. Often, the F-statistic is used to compare the residual variance of a sample with the mean residual variance of the class. (32) Employing the F-statistic, an upper limit for the residual variance can be calculated for those samples belonging to the class. The final result is a set of probabilities of class-membership for each sample.

An attractive feature of SIMCA is that a principal component mapping of the data has occurred. Hence, samples that may be described by spectra or chromatograms are mapped onto a much lower dimensional subspace for classification. If a sample is similar to the other samples in the class, it will lie near them in the principal component map defined by the samples representing that class. Another advantage of SIMCA is that an unknown is only assigned to the class for which it has a high probability. If the residual variance of a sample exceeds the upper limit for every modeled class in the data set, the sample would not be assigned to any of the classes because it is either an outlier or comes from a class that is not represented in the data set. Finally, SIMCA is sensitive to the quality of the
data used to generate the principal component models. As a result, there are diagnostics to assess the quality of the data, such as the modeling power and the discriminatory power. The modeling power describes how well a variable helps the principal components to model variation, and discriminatory power describes how well the variable helps the principal components to classify the samples in the data set. Variables with low modeling power and low discriminatory power are usually deleted from the data because they contribute only noise to the principal component models.

SIMCA can work with as few as 10 samples per class, and there is no restriction on the number of measurement variables, which is an important consideration, because the number of measurement variables often exceeds the number of samples in chemical studies. Most standard discrimination techniques would break down in these situations because of problems arising from collinearity and chance classification.

4.3 Feature Selection

Feature selection is a crucial step in KNN or SIMCA, because it is important to delete features or measurements that contain information about experimental artifacts or other systematic variations in the data not related to legitimate chemical differences between classes in a data set. For profiling experiments of the type that are being considered (see section 4.4) it is inevitable that relationships may exist among sets of conditions used to generate the data and the patterns that result. One must realize this in advance when approaching the task of analyzing such data. Therefore, the problem is utilizing information contained in the data characteristic of the class without being swamped by the large amount of qualitative and quantitative information contained in the chromatograms or spectra about the experimental conditions used to generate the data. If the basis of classification for samples in the training set is other than desired group differences, unfavorable classification results for the prediction set will be obtained despite a linearly separable training set. The existence of these confounding relationships is an inherent part of profiling data. Hence, the goal of feature selection is to increase the signal-to-noise ratio of the data by discarding measurements on chemical components that are not characteristic of the source profile of the classes in the data set. Feature selection in the context of pattern recognition is described in greater detail in the next section by way of the two worked examples.

4.4 Case Studies

Pattern recognition is about reasoning, using the available information about the problem to uncover information contained within the data. Autoscaling, feature selection, and classification are an integral part of this reasoning process. Each plays a role in uncovering information contained within the data.

Pattern recognition analyses are usually implemented in four distinct steps: data preprocessing, feature selection, classification, and mapping and display. However, the process is iterative, with the results of a classification or display often determining a further preprocessing step and reanalysis of the data. Although the procedures selected for a given problem are highly dependent upon the nature of the problem, it is still possible to develop a general set of guidelines for applying pattern recognition techniques to real data sets. In this section, a framework for solving the class-membership problem is presented by way of two recently published studies on chromatographic fingerprinting of complex biological and environmental samples.

4.4.1 Fuel Spill Identification

The first study involves the application of gas chromatographic and pattern recognition (GC/PR) methods to the problem of typing jet fuels, so that a spill sample in the environment can be traced to its source. The test data consisted of 228 gas chromatograms of neat jet fuel samples representing the major aviation fuels (JP-4, Jet-A, JP-7, JPTS, and JP-5) found in the USA. The neat jet fuel samples used in this study were obtained from Wright Patterson Air Force Base or Mulkiteo Energy Management Laboratory (Table 6). They were splits from regular quality control standards, which were purchased by the United States Air Force (USAF) to verify the authenticity of the manufacturer’s claims.

The prediction set consisted of 25 gas chromatograms of weathered jet fuels (Table 7). Eleven of the 25 weathered fuels were collected from sampling wells as a neat oily phase found floating on top of the well water. Eleven of the 25 weathered fuel samples were extracted from the soil near various fuel spills. The other three fuel samples had been subjected to weathering in a laboratory.

The neat jet fuel samples were stored in sealed containers at −20°C. Prior to chromatographic analysis, each fuel sample was diluted with methylene chloride.

and injected onto a fused silica capillary column (10 m × 0.10 mm) using a split injection technique. The fused silica capillary column was temperature programmed from 60 °C to 270 °C at 18 °C min⁻¹. High-speed gas chromatograms representative of the five fuel types (JP-4, Jet-A, JP-7, JPTS, and JP-5) are shown in Figure 15.

The gas chromatograms were peak matched using a computer program (36) that correctly assigned peaks by first computing the Kovats retention index (KI) (37) for compounds eluting off the GC column. Because the n-alkane peaks are the most prominent features present in the gas chromatograms of these fuels, it is a simple matter to compute KI values. The peak-matching program then developed a template of peaks by examining integration reports and adding peaks to the template that did not match the retention indices of previously observed peaks. By matching the retention indices of the peaks in each chromatogram with the retention indices of the features in the template, it was possible to produce a data vector for each gas chromatogram. Each feature in a peak-matched chromatogram was assigned a value corresponding to the normalized area of the peak in the chromatogram. (If the peak was present, its normalized area from the integration report was assigned to the corresponding element of the vector. If the peak was not present, the corresponding feature was assigned a value of zero.)

The number of times a particular peak was found to have a nonzero value was also computed, and features below a user-specified number of nonzero occurrences (which was set equal to 5% of the total number of fuel samples in the training set) were deleted from the data set. This peak-matching procedure yielded a final cumulative reference file containing 85 features, though not all peaks were present in all chromatograms.

Because outliers have the potential to adversely influence the performance of pattern recognition methods, outlier analysis was performed on each fuel class in the training set prior to pattern recognition analysis. The generalized distance test (38) at the 0.01 significance level was implemented via SCOUT (39) to identify discordant observations in the data. Three Jet-A and four JP-7 fuel samples were found to be outliers and were subsequently removed from the data set. The training set, comprising 221 gas chromatograms of 85 peaks each, was analyzed using pattern recognition methods. Prior to pattern recognition analysis, the data were autoscaled so that each feature had a mean of zero and standard deviation of one within the set of 221 gas chromatograms. Hence, each gas chromatogram was initially represented as an 85-dimensional data vector, \( \mathbf{x} = (x_1, x_2, x_3, \ldots, x_j, \ldots, x_{85}) \), where \( x_j \) is the normalized area of the \( j \)th peak.

The first step in the study was to apply PCA to the training set data. Figure 16 shows a plot of the two largest principal components of the 85 GC peaks obtained from the 221 neat jet fuel samples. Each fuel sample or gas chromatogram is represented as a point in the principal component map of the data. The JP-7 and JPTS fuel samples are well separated from one another and from the gas chromatograms of the JP-4, Jet-A, and JP-5 fuel samples, suggesting that information about fuel type is

present in the high speed gas chromatograms of the neat jet fuels. However, the overlap of the JP-5 and Jet-A fuels in the principal component map suggests that gas chromatograms of these two fuels share a common set of attributes, which is not surprising in view of their similar physical and chemical properties. Mayfield and Henley have also reported that gas chromatograms of Jet-A and JP-5 fuels were more difficult to classify than gas chromatograms of other types of jet fuels. Nevertheless, they concluded that fingerprint patterns exist within GC profiles of Jet-A and JP-5 fuels characteristic of fuel type, which is consistent with a plot of the second and third largest principal components of the training set data. The plot in Figure 17 indicates that differences do indeed exist between the GC profiles of Jet-A and JP-5 fuels. However, the second and third largest principal components do not represent the direction of maximum variance in the data. (In fact, they only represent 23.1% of the total cumulative variance or information content of the data.) Hence, it must be concluded that the bulk of the information contained within the 85 GC peaks is not about differences between the GC profiles of Jet-A and JP-5 fuels.

To better understand the problems associated with classifying the gas chromatograms of Jet-A and JP-5 fuels, it was necessary to reexamine this classification problem in greater detail. Figure 18 shows a plot of the two largest principal components of the 85 GC peaks of the 110 Jet-A and JP-5 neat fuel samples. It is evident from an examination of the principal component map that Jet-A and JP-5 fuel samples lie in different regions, suggesting that Jet-A and JP-5 fuels can be differentiated from each other on the basis of their GC profiles. However, the points representing the JP-5 fuels form
The subclustering suggests a lack of homogeneity among the samples representing the JP-5 fuels. Therefore, it is important to identify and delete the GC peaks responsible for the subclustering of the JP-5 fuels.

The following procedure was used to identify the GC peaks strongly correlated with the subclustering. First, the JP-5 fuel samples were divided into two categories on the basis of the observed subclustering. Next, the ability of each GC peak alone to discriminate between the gas chromatograms from the two JP-5 subclusters was assessed. The dichotomization power of each of the 85 GC peaks was also computed for the following category pairs: JP-5 versus JP-4, JP-5 versus Jet-A, JP-5 versus JP-7, and JP-5 versus JPTS. A GC peak was retained for further analysis only if its dichotomization power for the subclustering dichotomy was lower than for any of the other category pairs. Twenty-seven GC peaks that produced the best classification results when the chromatograms were classified as Jet-A, JPTS, JP-7, or JP-5 were retained for further study.

Figure 19 shows a plot of the two largest principal components of the 27 GC peaks obtained from the 221 neat jet fuel samples. It is evident from the principal component map of the 27 features that the five fuel classes are well separated. Furthermore, the principal component map of the data does not reveal subclustering within any class. This indicates that each fuel class is represented by a collection of samples that are in some way similar when the 27 GC peaks are used as features.
A five-way classification study involving JP-4, Jet-A, JP-7, JPTS, and JP-5 fuels was also undertaken using SIMCA. A principal component model for each fuel class in the training set was developed from the 27 GC peaks. The complexity of the principal component model was determined directly from the data using the technique of cross-validation. For each class, a single principal component was used to model the data. The gas chromatograms in the training set were then fitted to these models, and the residual – that is the sum of the squares difference between the original gas chromatogram and the chromatogram reproduced by the model – was computed for each gas chromatogram.

Each gas chromatogram in the training set was then classified on the basis of its goodness of fit. The probability for each gas chromatogram. The probability for each gas chromatogram reproduced by the model – was computed for the difference between the original gas chromatogram and the chromatogram for which it had the lowest variance ratio. However, if the variance ratio exceeds the critical $F$-value for that class, then the sample would not be assigned to it. Results from the five-way classification study involving the training set samples are summarized in Table 8. The recognition rate for JP-4, Jet-A, JP-7, and JPTS fuels is very high. However, Jet-A is more difficult to recognize due to its similarity to JP-5, which is undoubtedly the reason for SIMCA classifying 16 Jet-A fuel samples as JP-5.

The ability of the principal component models to predict the class of an unknown fuel was first tested using a method called internal validation. The training set of 221 gas chromatograms was subdivided into 13 training set – prediction set pairs. Each training set had 204 gas chromatograms and each prediction set had 17 gas chromatograms. The members of the sets were chosen randomly. Furthermore, a particular chromatogram was present in only 1 of the 13 prediction sets generated. Principal component models were developed for each of the training sets and tested on the corresponding prediction set. The mean classification success rate for these so-called prediction sets was 90.5%.

To further test the predictive ability of the 27 GC peaks and the classification models associated with them, an external prediction set of 25 gas chromatograms was employed. The gas chromatograms in the prediction set were run a few months before the neat jet fuel gas chromatograms were run. The results of this study are shown in Table 9. All the weathered fuel samples were correctly classified. This is an important result, as the changes in composition that occur after a jet fuel is released into the environment constitute a major problem in fuel spill identification. These changes may arise from evaporation of lower-molecular-weight alkanes.

$^a$ Classifications were made on the basis of the variance ratio
$F = [s_i^2/S_p^2][N_q − NC − 1]$, where $s_i^2$ is the residual of sample $p$ for class $i$, $S_p^2$ is the variance of class $i$, $N_q$ is the number of samples in the class, and NC is the number of principal components used to model the class. A sample is assigned to the class for which it has the lowest variance ratio. However, if the sample’s variance ratio exceeds the critical $F$-value for the class, then the sample cannot be assigned to the class. The critical $F$-value for each training set sample is $F_0.975 [(M − NC)(M − NC)(N_q − NC − 1)]$ where $M$ is the number of measurement variables or GC peaks used to develop the principal component model.

$^b$ Misclassified Jet-A and JP-5 fuel samples were categorized as JP-5.

$^a$ An object is assigned to the class for which it has the lowest variance ratio. However, if the variance ratio exceeds the critical $F$-value for that class, then the object cannot be assigned to it. Critical $F$-values of prediction set samples are obtained using one degree of freedom for the numerator and $N_q − NC − 1$ degrees of freedom for the denominator. $F(1, 52) = 5.35$, and it is $F(1, 41) = 5.47$ for JP-5.
microbial degradation, and the loss of water-soluble compounds due to dissolution.\footnote{42} Because the weathered fuel samples used in this study were recovered from a subsurface environment, loss of lower alkanes due to evaporation will be severely retarded. Furthermore, dissolution of water-soluble components should not pose a serious problem as only a small fraction of the fuel’s components is soluble in water.\footnote{43} Hence, the predominant weathering factor in subsurface fuel spills is probably biodegradation, which does not appear to have a pronounced effect on the overall GC profile of the fuels. Clearly, weathering of aviation turbine fuels in a subsurface environment will be greatly retarded compared to surface spills, thereby preserving the fuel’s identity for a longer period of time.

4.4.2 Africanized Honeybees

GC/PR has also been used to develop a potential method for differentiating Africanized honeybees from European honeybees.\footnote{44–47} The test data consisted of 109 gas chromatograms (49 Africanized and 60 European) of cuticular hydrocarbons obtained from bodies of Africanized and European honeybees. Cuticular hydrocarbons were obtained by rinsing the dry or pinned bee specimens in hexane for approximately 15 min. The cuticular hydrocarbon fraction analyzed by gas chromatography was isolated from the concentrated washings by means of a silicic acid column. Hexane was used as the eluent. The extracted hydrocarbons (equivalent to 4% of a bee) were coinjected with authentic \( n \)-alkane standards. KIs were assigned to compounds eluting off the column. These indices were used for peak identification.

Each gas chromatogram contained 40 peaks corresponding to a set of standardized retention time windows. A typical GC trace of the cuticular hydrocarbons from an Africanized honeybee sample is shown in Figure 20. The GC column had about 5000 plates. The hydrocarbon extract was analyzed on a glass column (1.8 m \( \times \) 2 mm) packed with 3% OV-17 on Chromosorb\textsuperscript{\textregistered} WAW DMCS packing (120–140 mesh).

The gas chromatograms were translated into data vectors by measuring the area of the 40 GC peaks. However, only 10 of the GC peaks were considered for pattern recognition analysis. Compounds comprising these peaks were found in the wax produced by nest bees, and the concentration pattern of the wax constituents is believed to convey genetic information about the honeybee colony. Because the feature selection process was carried out on the basis of a priori considerations, the probability of inadvertently exploiting random variation in the data was minimized.

Each gas chromatogram was normalized to constant sum using the total integrated area of the 40 GC peaks. Also, the training set data were autoscaled to ensure that each feature had equal weight in the analysis. The normalized and autoscaled data were then analyzed using KNN, which classifies the data vectors in the training set according to a majority vote of its KNNs. Hence, a sample will be classified as an Africanized or European bee only if the majority of its KNNs in the measurement space are Africanized bees. When the 1-nearest neighbor classification rule was applied to the 10 GC peaks, it could correctly classify every chromatogram in the training set. This result indicates that Africanized and European bee specimens are well separated from each other in the feature space defined by the 10 GC peaks.

To test the predictive ability of these descriptors and the classifier associated with them, a prediction set of 55 gas chromatograms (15 Africanized and 40 European) was employed. The distances between the prediction set samples and the samples in the training set were calculated, with class assignments computed in the same manner as in the training phase. Using the 1-nearest neighbor classification rule, a classification success rate of 100% was achieved for the gas chromatograms in the prediction set. This result
is important because it demonstrates that information derived solely from cuticular hydrocarbons can categorize bees as to subspecies. This suggests a direct relationship between the concentration pattern of these compounds and the identity of the subspecies (Africanized or European). Clearly, these results imply that GC/PR can be used to identify the presence of the African genotype in honeybees.

5 SOFTWARE

There are a number of Windows 95/98 software packages sold by commercial vendors that can be used for clustering and classification. UNSCRAMBLER (Camo A/S, Olav Trygvgasonsst. 24, N-7011 Trondheim, Norway) offers data preprocessing, PCA, SIMCA classification, and graphics in a flexible package. Pirouette (Infometrix Inc., P.O. Box 1528, 17270 Woodinville-Redmond Road NE, Suite 777, Woodinville, WA 98072-1528) has a nice user interface, with good quality graphics. The package has data preprocessing, hierarchical clustering, PCA, KNN, and SIMCA classification. Pirouette, which has been validated according to the United States Food and Drug Administration Standard Operating Procedure, is a good introductory package because of its broad functionality.

SCAN (Minitab Inc., 3081 Enterprise Drive, State College, PA 16801-3008) has PCA, hierarchical clustering, KNN, SIMCA, and discriminant analysis (quadratic, linear, regularized, and DASCO, which is an advanced classification method in chemometrics). The user interface, which is similar to the popular Minitab statistics package, has many advanced editing features, such as brushing. The package is a good mix of statistical and pattern recognition methods. SIRIUS (Pattern Recognition Associates, P.O. Box 9280, The Woodlands, TX 77387-9280) is a graphics oriented package intended for modeling and exploratory data analysis, such as SIMCA and PCA. The PLS TOOLBOX (Eigenvector Technologies, P.O. Box 483, 196 Hyacinth, Manson, WA 89931) is for Matlab and contains routines for PCA, discriminant analysis, and cluster analysis.

6 CONCLUSION

In this article, a basic methodology for analyzing large multivariate chemical data sets is described. A chromatogram or spectrum is represented as a point in a high-dimensional measurement space. Exploratory data analysis techniques (PCA and hierarchical clustering) are then used to investigate the properties of this measurement space. These methods can provide information about trends present in the data. Classification methods can then be used to further quantify these relationships. The techniques, which have been found to be most useful, are nonparametric in nature. As such, they do not attempt to fit the data to an exact functional form; rather, they use the data to suggest an appropriate mathematical model, which can identify structure within the data. Hence, the approach described in this article relies heavily on graphics for the presentation of results, because clustering and classification methods should be used to extend the ability of human pattern recognition to uncover structure in multivariate data. Although the computer can assimilate more data at any given time than can the chemist, it is the chemist, in the end, who must make the necessary decisions and judgements about their data.

List of Symbols
Multivariate calibration (MVC) is a methodology for using multiple signals, for instance a digitized spectrum, to determine the levels of concentrations of chemical compounds in analytical samples. MVC can also be used to determine other properties of interest, for instance viscosity, particle size distribution, energy content, or taste. MVC is made in two phases. In the first, the “training” or “calibration” phase, samples with known concentration (property) values and their signal profiles are used to develop a model of their relationship, a multivariate standard curve. In the second phase, this model is used with new samples to determine their concentration (property) values from their signal profiles.

1 INTRODUCTION

The calibration of an analytical instrument means the construction of a quantitative relationship between, on the one hand the instrument “signals” as they are measured on analytical samples, and on the other hand one or several properties of the samples, usually concentrations of analytes in the samples.

In univariate calibration (UVC) the amplitude of one signal, e.g. the absorption of light at a certain wavelength, is related to the concentration of one analyte. In MVC, several signals, for instance from a whole spectrum digitized at regularly spaced wavelengths, are used to derive a multivariate model (a generalized standard curve). This model simultaneously relates the amplitudes of all the signals, or a substantial part of them, to the concentrations of one or several analytes in the samples. The multivariate model is then used to estimate the analyte concentrations in new samples from the multiple signals measured on these. The use of MVC and spectral profiles to “measure” concentrations or other properties is often referred to as “indirect measurement” in contrast to the direct measurement of, say, concentration by means of titration, or precipitation and weighing.

In both UVC and MVC, the deviations between the model and the data are used to derive statistical measures of uncertainty of the model and of the estimated concentrations of the new samples. In MVC, the multivariate information can be used for additional statistical diagnostics such as the similarity between a new sample and the calibration set (CS), the presence of clusters in the data, and the relative information content of the “signals” (predictor variables).

The relation between spectroscopic signals and concentrations is fairly linear as long as the variation of concentration is moderate. This is often referred to as Lambert–Beer’s law. Most calibrations are limited to concentration intervals where a linear standard curve is adequate, but the extension to mildly nonlinear curves are straightforward using, for instance, quadratic polynomials as the functional basis.

MVC has six steps, the first five of which comprise the training phase, and the sixth is the prediction phase. These steps are:

1. Specification of the analytes with concentration ranges. Selection of the instrumental method, including the range of wavelengths, reflectance or transmission mode, etc.
2. Selection of a representative set of calibration samples – the training set (TS) or CS. This CS should span the range of analyte concentrations and also the concentration ranges of interferents.
3. The multivariate signals (typically the digitized spectra) are recorded for the calibration samples and stored in an appropriate data base. The analyte concentrations are measured by a reference method.
4. The data are investigated for the presence of outliers and other anomalies. Thereafter, the data are preprocessed and transformed to a form suitable for the subsequent data analysis.
5. The calibration model is developed and optimized. This includes checking for linearity, and the determination of selectivity, detection limits, precision, accuracy, and other measures of performance. Statistical measures of uncertainty are calculated and used to construct confidence intervals for predicted values. Also, the model is interpreted chemically, important variables (wavelength regions) looked at, interferences are identified, etc.
6. The model is used to estimate the analyte concentrations in new samples (prediction set), including confidence intervals. Diagnostics for dissimilarity (outliers) are checked.

MVC has a much improved precision and selectivity compared to UVC. Also MVC can handle complicated samples with unknown interfering compounds, and it works even when there is no selective wavelength region for the analyte. This has made MVC particularly useful with nonselective spectral methods, such as near-infrared spectroscopy (NIR). In a slightly generalized sense, MVC can be applied to the relation between any instrumental “profile”, including chromatograms, kinetic curves, thermo-gravimetric curves, sound spectra, etc. and any properties of the analyzed sample. The
properties can be other than concentrations, for instance viscosity and molecular weight of polymer samples, the energy content of oil, gasoline, coal, or peat, or the taste of cheese, wine, or beer. Hence the MVC methodology provides exciting possibilities for the indirect measurement of complicated properties of complicated samples.

1.1 Univariate Calibration

The idea of calibration is simple and powerful. The instrument is given a training or CS of samples with known concentration \(c_i\) of the analyte, and the amplitude of the instrument signal \(z_i\) is recorded for each sample, \(i\). The resulting data \((z_i, c_i, i = 1, 2, \ldots, n)\) are then used to construct a standard curve (usually a straight line), which is used for new samples to predict the concentration for new samples from the amplitude of the signal measured on these samples (Figure 1).

A prerequisite for calibration to work is that the signal amplitude really changes in a reproducible way with the analyte concentration. The greater this change is for a unit change of concentration, the greater is the sensitivity of the instrument with respect to the analyte. Moreover, the signal must not be much affected by other components in the sample, it must be fairly selective.

\[ z_i = a + bc_i + e_i \] (1)

Least squares (linear regression) is normally used for this calculation.\(^2\) The residuals \(e_i\) are calculated, with their variance \((s^2)\) and standard deviation (SD), \(s\), (Equations 2 and 3).

\[ e_i = z_{\text{observed}} - z_{\text{model}} \] (2)

\[ s = \sqrt{\frac{\sum e_i^2}{n-1}} \] (3)

This residual standard deviation (RSD) should be the same as the precision of measurement within statistical uncertainty. Regression\(^2\) is then used to calculate standard errors and confidence intervals for the parameters, as well as for the concentrations of new samples (calculated from their signal amplitudes and the standard curve). If the RSD is substantially different at different concentrations, a weighted regression may be needed for an efficient data analysis. It should be noted that the estimation of the parameters \((a, b\) in Equation 1) by regression, is not based on the assumption of constant and normally distributed noise. The sizes of their confidence intervals depend, however, on the distribution of the noise.

1.3 Multivariate Calibration; Many Signals

In MVC the whole spectral profile is used for the calibration instead of just the signal at one single wavelength.\(^1\) The signal data now consists of a matrix, \(Z\) (dimension \(n \times K\)). In MVC, one can calibrate on a single analyte, i.e. \(y\) is an \((n \times 1)\) vector, or one can simultaneously calibrate on several \((M)\) analytes. In the latter case, the concentrations of the CS form an \((n \times M)\) matrix, \(Y\). The latter is discussed in sections 3.5 and 8.3.

1.4 Interferences

In most calibrations, the samples contain compounds other than the actual analyte, so-called interferents. These other compounds will most likely also affect the signal, and hence the measured signal will have a systematic bias, an interference. UVC thus works well only when the signal is close to selective, and is affected only by the change of the analyte concentration. This often necessitates the use of chromatography or some other separation method.
to clean up the sample from interfering compounds. MVC is affected much less by the presence of other compounds due to its ability to find nearly selective combinations of the multiple signals that model and predict the analyte concentration(s). A preprocessing of the data to enhance this selectivity may still be needed (see section 7).

A second problem is that any calibration model is valid only for samples that are similar to the calibration samples. Thus for example, a model developed for gold in seawater samples, does not give accurate results for fresh water samples, and even less well with samples of orange juice. Hence one should check that each new sample is indeed similar to the calibration samples. Unfortunately, there is nothing in the single signal employed in UVC that is helpful for this matter, and the similarity must be checked in some other way, or accepted by faith. In MVC, however, the profile of the multiple signals contains information also about the similarity between the samples. Hence, MVC provides an “autodiagnosis” for the similarity between the new samples and the calibration samples, which greatly improves the reliability of the results.¹¹

### 1.5 Direct and Indirect Calibration

If the spectra of all the pure constituents are available (denoted by \( r_{jk} \) for the spectral amplitude of constituent \( j \) at wavelength \( k \)), the concentrations \( c_{ij} \) in sample \( i \) can be estimated from the spectrum \( z_i \) of a mixture of the analytes by means of multiple regression using the linear model (Equation 4):

\[
z_i = \sum_j r_{jk} c_j + e_i \quad (4)
\]

This is often called direct calibration because the causal physical model (concentration \( \rightarrow \) spectrum) and the statistical model \( (z = f(c)) \) coincide.¹¹ This direct approach works when (a) all constituents in a given sample are known together with their spectra, and (b) the spectrum of any constituent is the same when it is pure and when it is present in the mixture (sample). This makes direct calibration work for simple and rather dilute gas samples and some simple dilute liquid samples, but less well or not at all with complicated samples where many constituents are unknown (interferents) and where the spectra change with concentration. This is exemplified by samples of grain, blood, tissue, lake sediment, polymer formulations, pharmaceutical formulations, wood, pulp, etc. where indirect MVC is the only feasible approach.

The MVC model is formulated inversely to the direct model above, with the explicit objective to predict the concentrations \( (Y) \) from the digitized and preprocessed spectra \( (X) \), (Equation 5):

\[
Y = XB + F \quad (5)
\]

Here the information flow (from \( X \) to \( Y \)) is the opposite to the causal model \( (Y \rightarrow X) \), which made this be called the “indirect calibration” model. This inverse formulation of the calibration model was first proposed by Krutchoff,⁶ causing much initial consternation and controversy. With the work of Hoadley,⁷ Naes,⁸ and others, however, we have learnt to distinguish between the direction of the information flow and the direction of causality, and (indirect) MVC is today established and accepted as a good working approach.

The mechanism of inverse MVC is, quite simply, that as long as the correlation structure between \( X \) (signals) and \( Y \) (concentrations, properties) remains, then the predictions can be made in either direction \( X \rightarrow Y \), or \( Y \rightarrow X \). The principle of MVC is to utilize this fact in the direction \( X \rightarrow Y \) (signals predict concentrations or properties). The correlation structure of \( (X,Y) \) is constant as long as the samples are similar to each other, but it changes when very different samples are brought in. Hence the CS must be representative for the future samples for which the concentrations or other properties are to be determined, see section 4.

### 1.6 The Concentrations of Two Drug Compounds Determined by Ultraviolet Spectroscopy

To illustrate the calculations and the interpretation of resulting parameters, we shall use a small example with ultraviolet (UV) spectra of samples containing two drug substances. There is a set of \( n = 10 \) spectra of mixed standards, where all combinations of three levels of two substances (felodipine and metoprolol) are included. One of the samples is included in duplicate (#6 and 7). Three additional samples are included as a prediction set. In addition, the spectra of the two pure substances are included, showing overlap with no selective region for metoprolol, but a selective region of felodipine with a maximum at around variable 58, corresponding to around 363 nm (Figure 2).

![Figure 2 UV Spectra of felodipine (-----) and metoprolol (——) (pure samples 11 and 12).](Image)
UV spectra in the wavelength range 250 to 450 nm have been recorded, and digitized at every 2 nm giving \( K = 101 \) spectral variables per sample. The concentration intervals are 20–29 \( \mu \text{g L}^{-1} \) for the first substance (felodipine) and 191–239 \( \mu \text{g L}^{-1} \) for the second (meto-prolol).

### 1.7 Mathematical and Statistical Formulation

Assuming that the signal amplitudes change proportionally to the concentrations (Lambert–Beer’s law), the calibration model will be linear, with \( \mathbf{B} \) a matrix of parameters to be determined in the calibration stage.

\[
\mathbf{Y} = \mathbf{ZB} + \mathbf{F}
\]

The model (Equation 6) works as a multivariate standard curve, where the parameters \( \mathbf{B} \) define directions in the \( \mathbf{Z} \)-space (the space of the spectral variables) which are linearly related to the \( \mathbf{Y} \)-variables, i.e. the analyte concentrations or other properties of interest.

The \( \mathbf{Y} \)-residual vector or matrix \( \mathbf{F} \) contains the deviations between model and the concentration/property values (\( \mathbf{Y} \)), and should have small elements everywhere. The size of the elements in \( \mathbf{F} \) is determined by the precision of the instrument, the experimental control, the adequacy of the linear model and the method of data analysis. These residuals can be inspected for large values (outliers) and systematic patterns, which indicate model inadequacies. The SD of these \( \mathbf{Y} \)-residuals should not greatly exceed the known precision of the used method and instrument.

In the case where Equation (6) is estimated by a projection model (section 8) this allows also the estimation of residuals of the (preprocessed) signals, \( \mathbf{X} \). These residuals, denoted \( \mathbf{E} \), provide indications of spectral areas with large and small information content.

### 2 NOTATION AND ABBREVIATIONS USED IN MULTIVARIATE CALIBRATION

#### 2.1 Mathematical Notation

Vectors are denoted by bold lower-case letters, e.g. \( \mathbf{t} \), and matrices by bold capital letters, e.g. \( \mathbf{X} \). Vectors are assumed to be column vectors unless indicated by a prime (transpose), e.g. \( \mathbf{p}' \). The length (norm) of a vector or a matrix is denoted by \( ||v|| \) or \( ||X|| \) respectively. This length divided by the square root of the number of elements, often corrected for the degrees of freedom, is the SD of the vector or the matrix.

For notation see the list of symbols.

### 3 PROBLEM FORMULATION AND CHOICE OF ANALYTICAL METHOD

MVC provides an improved set of tools for analytical chemistry compared to UVC. There is no longer a need to find the “ultimate variable” with as little interference as possible. One or a few analytical techniques yielding several variables that carry relevant information for the analysis are preferred. Interferences can be compensated for, a measure of the appropriateness of using an MVC for a given sample is available, and the correlation patterns among the variables are a starting point for new knowledge.

By treating analytical data from a given sample as a profile of variables, where the profile is used as a total signature of the sample, there is less need for special optimization regarding the protection of the single variable from interfering compounds and processes. For efficient use, the focus should be on analytical methods that give several variables with a short measurement time. The measurements should be made using best analytical chemistry practice.

A number of questions are closely related to the MVC problem, but we will here only discuss the first, namely (1) How much of a known compound is present in the given sample? Another, more demanding question is: (2) Which compounds are present in the given sample? An even more elusive type of questions is: (3) Will this intermediate product yield a good-quality end product?: e.g. Will this wine be better with storage? Finally, there is a related question of classification that in some cases is easier to answer if the amount of reference samples is limited: (4) Is the analytical profile in the present sample similar to that of the previous samples?

#### 3.1 How Much of a Known Compound is Present in the Given Sample?

The type 1 question has traditionally been answered with UVC. The use of UVC in this case implies that the signal is selective, i.e. the interfering compounds in the sample matrix must have a low influence on the magnitude of the signal. This is today often accomplished by a chromatographic separation step. By using MVC it is possible to omit the chromatographic separation before a spectrometric detection. This will save run time for a long series of determinations and even allow for direct measurements on solid materials, thus avoiding the time spent for sample preparation. The recognition of aberrant samples usually attained by visual inspection of chromatograms, can be automated in MVC. The spectral residual profile provides this ability.
3.2 Prepared Reference Samples, or Use of a Reference Method

We can distinguish two calibration situations, the first where reference samples can be prepared with desired levels of analytes and interferents, and the second where samples are collected from nature or some process of interest, and analyzed by a reference method. In statistics this is referred to as the concentrations being fixed or random, respectively.

The first situation is illustrated by the example (section 1.6), where two known substances are weighed and dissolved to make reference samples of known composition. The concentration levels in these samples should then be laid out according to a statistical design, typically a full or fractional grid design with five or more levels. The second situation is typical for complicated samples, such as samples of grain where one wishes to determine the concentrations of protein, fat, and water. Then many samples are needed in the TS to ensure the proper spanning of all important directions in the concentration space, and to compensate for the imprecision of the reference method.

The reference method should have good accuracy and precision, providing accurate reference values for the TS and the validation set. Effectively the second type of MVC involves an inter-calibration of two different analytical methods that puts both the MVC and the reference method in a critical light. This is not always in favor of the reference method and it may need improvement in order to yield high-quality data.

3.3 Multivariate Calibration for Explorative Work

Often the objective is not to build a precise calibration but rather to explore the correlations between variables investigated in development work. In this case the MVC is used in an inductive way to make steps forward in the building of knowledge during explorative work. Here the resulting information is the structure of the calibration model rather than the specific amount of a compound. This use of MVC is less obvious but very important in industrial development work.

A much more rough calibration can then be made based on a minimal number of samples, just to give an idea about the feasibility of the methodology. Here the minimum number of samples is five, and these samples must also be well distributed over the range of interest. With so few samples and with many spectral variables, no extensive preprocessing can be afforded, and the partial least squares (PLS) projection to latent structures approach is preferred.

3.4 Multivariate Classification of Samples in Narrow Concentration Intervals

In some cases it less practical to make a calibration, for instance, when the properties of an industrial product are going to be monitored. The product is produced according to a specification aiming at a constant set of properties. Then a large set of samples is available with concentrations close to the specification in a very narrow distribution. Samples outside this narrow distribution may not be available from the production. Then calibration samples outside the specification have to be manufactured at lab scale in order to span a variation of the concentration that is needed for the TS. This may be feasible for liquid solutions with few components, but it is more involved for solid samples such as powders and pharmaceutical tablets.

An alternative approach in this case is to use multivariate classification. Then the classification is used as a positive verification of the presence of the correct concentration in a certain concentration interval. In the method validation step, concentrations outside this interval have to be tested and should fail a positive identity. Analogously to the residual variance in MVC, the classification residuals indicate aberrant spectra resulting from deviations from the specified composition profile.

Using multivariate classification in this way may save a lot of development time when it is costly to create concentration variations for the calibration samples, while it is still possible to get the benefit of using spectral residuals to find the sources for variations when they occur.

3.5 One or Several Analytes

When PLS is used in the MVC, it is possible to have more than one response from the same calibration model. This is useful in cases where the responses are correlated. When the reference method for one or a few correlated responses is performing less well, the use of a joint model can support the prediction of these responses. This is useful in explorative work when the most information has to be extracted from limited amounts of data.

When uncorrelated responses are used in the same model, this will need more PLS components than the corresponding single-response calibration models. Hence it is better in this case to develop separate PLS models for each response. Typical situations with correlated responses are exemplified by isocratic chromatography where the peak widths are correlated with the peak retention time, by environmental analysis where pollutants often vary together, and by kinetic measurements where the amount of reacted compound at time \( j \) is also correlated with the amount of reacted compound at time \( j - 1, j - 2, \) etc.
3.6 The Chemical Analytical Method

Analyte concentrations can be determined in various types of phases, i.e., transparent and turbid liquids, solids, gases, and plasma. Traditionally, most analyses have been performed in the liquid state and in some cases in the gas phase. If the sample came as a solid, it would be dissolved in an appropriate solvent and then analyzed. In chromatographic and electrophoretic separations the sample is also transported in solution or in the gas phase.

The technology for measuring absorbance by light passing through a liquid or gas sample cell is well established and yields close to linear responses in the appropriate concentration range. These optical transmission techniques are applicable for ultraviolet/visible (UV/VIS), NIR, infrared (IR), and their combinations with separation methods.

Transmission spectroscopy is limited by the amount of light that is coming through the sample. If the sample in the sample cell is absorbing too much light in some wavelength regions, the measurement at those wavelengths will be of little analytical value since stray light in the instrument will be the dominating feature. This may be adjusted by the cell path length. Technically it is more difficult to get a close to linear response at short wavelengths in UV below 210 nm due to absorption of glass and Rayleigh scattering due to dust. However, this is a range that is commonly used for amino acids and proteins.

When water is a solvent, IR spectrometry has to be done with very short path lengths in attenuated total reflection (ATR). For NIR transmission in water solutions, the proportion between the $\approx 1440\,\text{nm}$ and the $\approx 1930\,\text{nm}$ water peaks may be used as an indicator of nonlinearity. In many cases the longer wavelengths including the $1900\,\text{nm}$ peak have to be discarded to get a close to linear response.

For trace amounts of substances it is advantageous to employ fluorescence measurements to get a high sensitivity. Fluorescence data with both excitation and emission wavelengths collected is also a case where two-dimensional (2-D) MVC is working well.

With MVC it is also possible to use UV/VIS spectrometry in turbid solutions.$^{12}$ For NIR the turbidity is less of a problem due to the smaller spectral response for turbidity at longer wavelengths. If larger particles are present in the sample, the optics of the instrument has to have a wide enough beam to pass beside the particles. For optical fibers this means that when larger particles are present it is better with fiber bundles than single fibers. When the sample becomes too turbid it is advantageous to change from transmission to diffuse reflectance.

Solid samples also have polymorphic properties. These are destroyed if the sample is dissolved. Hence it is often of value to measure directly on solid samples. This can be done by IR, NIR or UV/VIS diffuse reflectance, NIR transmission, and Raman. X-ray diffraction is a possible reference method for MVC with polymorphic samples. For most complex solid samples measured with NIR, the MVC is the only way to get a calibration. NIR is working well with most organic solids but an exception is black plastics, which are better characterized with diffuse reflectance IR. Raman is also working for some inorganic solids.

Color measurement is a special form of UV/VIS diffuse reflectance with the colors as a standardized set of responses in a fixed instrument calibration.

Measurements in the gas phase are theoretically simpler, since there are less interactions between molecules than in the solid and liquid state. However, the equipment may become bulkier because of the longer cell paths needed to get sufficient sensitivity.

Measurements in plasma are done for example in inductively coupled plasma (ICP) and inductively coupled plasma/mass spectrometry (ICP/MS) where metal salts in solution are burnt in a plasma and the emission spectrum is measured, or the plasma is subsequently put into a mass spectrometer. The plasma is used to eliminate molecules and only keep the elemental responses from the excited atoms. Spectra are obtained in parallel with many elements. A potential for MVC exists with ICP and ICP/MS.

Spectroscopy is ideal for creating variables for MVC. One reason is the stability of the wavelength scale. MVC is dependent upon having the same information sorted into the same variables (wavelengths) over all measured samples. This generally holds when a single instrument is used for both calibration and prediction. For dispersive spectrometers such as UV/VIS, NIR, IR, and fluorescence and Raman, there are several levels of methods adapted for wavelength-scale verification and correction, all the way from using, for instance, a rare-earth oxide or polystyrene transmission or reflection standard manually during maintenance, to an automatic wavelength correction preceding each obtained spectrum. A frequent and automatic wavelength correction is preferable.

The photo diode array spectrometer (PDA) is a special case of the dispersive spectrometers where the grating is mounted in a fixed position. Due to the nonmoving parts, the PDA is suitable for fast data acquisition but is in general limited to narrower wavelength ranges and is less sensitive than the corresponding nonarray detector. For use with NIR the InGaAs array is presently emerging as a sensitive detector with high speed data acquisition in the $800–1700\,\text{nm}$ range, and also in extended versions up to $2300\,\text{nm}$.

For nuclear magnetic resonance (NMR) it is possible to use compounds with known resonating frequencies as internal standards for the frequency scale. In mass
spectrometry (MS), mass standards also have to be employed in order to verify and adjust the mass scale.

The wavelength scale may also be controlled by fixed or variable filters. Arrays of fixed filters have been designed for specific measurements, such as protein in wheat by NIR diffuse reflectance. In general, fixed filter instruments are considered to be less repeatable between instruments and filters tend to age faster than gratings. Another line of filter instruments uses acousto-optical tuneable filters (AOTF). This type of instrument is suitable when fast spectral acquisition is needed in process applications.

Even if MVC can cope with mild instrumental non-linearities, it is preferable to obtain spectra of good quality from analytical instruments with good specifications. If a certain variation is not present in the spectra, it will not be caught by the MVC either. However, the presence of a variation need not be visible for the human eye, e.g. a set of NIR spectra. MVC performs better than the human eye in catching small systematic variations that occur in combinations over a large number of wavelengths.

3.7 Spectral or Time Domain

The IR, NIR, NMR, and Raman spectrometers have developed to a state where spectra are often obtained as interferograms. Then Fourier transform (FT) is applied to translate the measured signals into spectra. For IR, NIR, and Raman the raw data for the wavelength or frequency scale is generated by a laser beam that passes through the same path as the analytical light in the spectrometer. By the use of interference fringes between the laser beams passing through the two different pathways in the spectrometer, it is possible to accurately define the relative position of the instrument mirrors and thus the frequency scale in the calculated spectrum. The precision of the wavelength scale from this type of instrument is generally high.

From an MVC point of view there may be alternative ways to treat the interferograms. They could be used directly as variables in an MVC or be preprocessed by, for instance, a wavelet transform. The main reason for the use of FT methods is that the spectra should be convenient to inspect one by one for the human eye. To accomplish this, the interferogram is usually premultiplied by a filter that has a slight smoothing effect before the FT is applied. Since MVC works also for patterns that are less interpretable by the human eye, this smoothing may not be necessary and may even remove some of the important spectral information.

When using MVC based on FT generated spectra, it is important to keep track of the filter used before the FT calculation. This filter should be the same for all spectra in a calibration. With a less smoothing filter, wiggles may occur on the spectral baseline. These may not show up in the spectra but will still be visible in PLS loading vectors.

3.8 Chromatography

Chromatographic and electrophoretic methods also yield a vector (i.e. a chromatogram) for each sample with peaks representing different compounds separated in time. Such vectors are useful for characterizing biological samples and their relation to properties such as flavor, taste, and degree of disease. Examples are gas chromatography (GC), liquid chromatography (LC) and thin-layer chromatography (TLC).

Just treating the chromatogram as a spectrum will not work well since the retention time axis of chromatograms varies with e.g. the column temperature, the mobile phase, the column age, and the column to column variation. Thus it is not straightforward to align chromatographic peaks. When there are few and known peaks, the peak areas or peak heights can be used provided that they are assigned correctly. Internal standards may be used as retention time reference points and also as a basis for the magnitude scale. When the whole chromatographic profile is important, such as for characterization of natural materials, e.g. oil, peat, and wine, it is more appropriate to use the entire chromatogram as a set of variables. Successful approaches for aligning the retention times have been reported. Alternatively, Fourier or wavelet transformation of the chromatographic profile may give a representation less sensitive to shifts in the chromatogram.

When quantitative measurements are based on image scanned TLC plates or electrophoretic gels it is important to recognize the limited resolution in magnitude which may cause a nonlinear response.

Often a separation is optimized to give an even separation of the peaks. This is not the optimal way to run a separation method when molecular properties are wanted. Instead the conditions should be selected to show interactions of different kinds such as hydrogen bonding, $\eta$–$\eta$ interaction, acid–base properties, etc. The interactions of a compound with a set of mobile and stationary phases may be used in an MVC for molecular properties, such as lipophilicity, polarity and other related chemical properties for a class of chemical compounds.

3.9 Combination Methods

The combination methods often use one method to separate the sample into purer fractions, followed by a spectrometric method to give as much information as possible about the separated fractions. The fractions may not always be pure compounds, they can also be combinations of related compounds. GC may be
combined with MS or IR; LC may be combined with MS or UV; tandem MS may be used.

In these cases spectral data may be directly used in MVC. Automated multivariate classification is a good primary step in order to align retention times. This will now be easier since each chromatographic peak also has a spectral profile.

Hyphenated methods also lend themselves to the next level of MVC, working with variables as 2-D arrays instead of vectors. Special MVC methods have been developed for this situation.\textsuperscript{(19,20)} However, when a chromatographic or electrophoretic separation method is involved, the time alignment problem in section 3.8.4 still persists.

### 3.10 Sensor Arrays (Electronic Noses, Crystal Sensors)

Sensor arrays are often constructed with silicon chip technology as resonators with a layer of substrate that is catching target molecules. The idea behind sensor arrays is that the individual sensor does not need to be totally selective, but through a combination of slightly different substrates, MVC is given the possibility to distinguish between different compounds. There are no alignment problems, but memory effects may be a problem, as the substrate may age and become chemically modified during harsh chemical conditions. When used for MVC these type of calibrations should have some means for shutting down individual sensors without too much degradation of the calibration performance.

### 3.11 Kinetic Curves

Kinetic measurements give a profile of variables that changes with time. Kinetic raw variables can be used in MVC as they are.

Another approach is to fit a physical kinetic model to the time traces and then use the coefficients of this model as variables in an MVC. In this case it is important that these coefficients really reflect a measured property and not just constitute an extrapolation. For example, an LD50 value will be an extrapolation in a toxicological study if the substance had such a low toxicity that the LD50 conditions were never approached in the study. In this case the LD10 or LD20 values are bracketed by measured values, and hence are more suitable for MVC.

### 3.12 Images and Other Measured Data

Two- or three-dimensional images from microscopes, digital cameras, tomography, etc. can all be transformed to data vectors and hence be used as data for MVC. Special preprocessing may be needed to make the data comparable between samples, such as 2-D FT or 2-D wavelet transforms. Actually, ordinary spectra UV, IR, etc.) can be considered as one-dimensional images, and quantitative image analysis can be considered as just a special case of MVC.\textsuperscript{(21)}

Any quantitative multivariate data measured on analytical samples can be used as the basis for MVC provided that they contain relevant information. Recently, profiles of sound and other vibrations have been shown to contain interesting information about concentrations, the degree of mixing and other properties of complex material flows.\textsuperscript{(22)}

### 4 SELECTION OF THE CALIBRATION SET

The calibration results in a model that relates the signal amplitudes to concentration, the so-called standard curve. All models have a domain of validity which depends on the mathematical stability of the model and the range of the data on which the model is based. The uncertainty of the predicted concentrations for a given signal amplitude increase rapidly outside the concentration range defined by the calibration samples (see Figure 1). Hence the calibration model (the standard curve) should not be applied far outside this range. Consequently, if one knows the future operating range of the analytical method, the calibration samples must span this range. The calibration sample concentrations should also be distributed fairly uniformly over the range of interest.

The precision of the standard curve improves with an increasing number of calibration samples, \( n \).\textsuperscript{(2−4)} With large \( n \), the uncertainty of the predicted concentrations is dominated by the uncertainty of the signal amplitude of the new samples. In the situation where reference samples are prepared from pure substances, there is therefore little gain in increasing \( n \) above around \( M \times 10 \) (\( M \) is the number of analytes), except for validation of linearity and for the estimation of the precision of measurement in different parts of the concentration interval.

In the situation where the concentration levels in the reference samples cannot be directly controlled, however, one needs a fairly large number of such samples for the calibration of the model to ensure representativity, typically thirty to several hundreds.\textsuperscript{(1,5)} In the subsequent data analysis one must also confirm that indeed the concentration space is appropriately represented.

The reference samples provide a TS of data where both the “signal matrix” \( X \) – usually consisting of a set of digitized spectra from NMR, NIR, FTIR, . . . – and the property matrix \( Y \) for the same samples (the
concentrations or other property values) are defined. These data provide the basic structure of the model, i.e. how the signals (digitized spectra) co-vary with the concentrations (or other properties) in the Y matrix.

4.1 Validation Set (Test Set)
To ensure that the calibration model works well in the desired concentration range(s), it is essential to validate the model by using it on a representative set of new samples – the validation set, often also called the test set. This is further discussed in section 9.

4.2 Prediction Set
The samples on which the developed model finally is used are often collectively called the prediction set. This set is often open ended and in principle infinite, and is usually not known or available at the time of the model development, the calibration.

5 MAKING THE MEASUREMENTS
This part is of course a most important part of the calibration. MVC is by no way a substitute for sloppy measurements. On the contrary, MVC shows the weakness of the data, and is negatively affected by imprecision, bad sampling, etc. just as UVC. Hence, the multivariate measurements must be made in a reproducible and precise way. This means, in turn, that the measuring conditions should be controlled to be as constant as possible, or at least carefully recorded, solvents should be checked, etc. i.e. normal analytical precautions should be taken also with MVC. See section 5.1.

5.1 Uncontrolled Variables
Uncontrolled variables such as temperature, humidity, time order, powder packing density, cell path length, etc. may affect the spectral response and in some cases the chromatographic retention. MVC can often compensate for variations in uncontrolled variables. This is achieved if the uncontrolled variable is allowed to vary in the calibration TS. The best form of such variation is according to a statistical experimental design. The variations could also be introduced as random variations. It is bad practice to try to keep all influencing variables constant in the calibration training and test sets, and thereafter relax the conditions in routine use. On the contrary, the calibration should contain slightly larger variations than expected in routine use in order to enter compensations for the interfering variations in the calibration model. If, for example, means to control the climate and precise powder packing devices are available during calibration time for a diffuse reflectance NIR method for powders, these should be used to induce known designed or random variations rather than keeping the conditions unrealistically constant.

5.2 Ambiguous Spectral Regions (Variables)
Together with high-performing variables, in general analytical instruments produce variables with bad performance in spectral regions that are technically available but of little analytical value. One example is when optical fibers are used together with a spectrometer. The original design of the spectrometer usually allows for measurements at wavelengths that are not coming through the optical fiber. Rather than resorting to automatic variable selection schemes, the analyst should take decisions in these cases and avoid using variables that are out of the analytical range.

5.3 Randomization of Measuring Order
It is good practice to make the measurements in random order when the training and test sets are made. It is not advisable to order the samples in the same or reversed order as the magnitude of the y-variable to be calibrated for. If the samples are ordered, changes that occur with time, such as instrument warming, operator learning, etc. will introduce a bias in the calibration.

When trace amounts of compounds are to be measured, this randomized measuring order is not always practical. In these cases the samples may have to be grouped to reduce carry over. However, extra diagnostics must be applied to verify that the measurements are not correlated with time. This can be done with an explorative MVC with the actual time or the run order for the measurement as the response to the measured variables.

5.4 Data Collection and Administration
Data suitable for import into for MVC software are usually organized as tables or matrices where each row holds the measured values for one sample. These row vectors are also commonly called objects or observations. Each column in the table holds the measurements of a specific variable. Each object and variable should be identified by a name (label) in ASCII text format. When the objects are spectra, it is useful to attach the spectral scale to the data table. This may be done in the name fields of the variables or as a separate object.
6 INITIAL QUALITY CONTROL OF THE DATA

In any data set there is a risk of bad measurements, fouled samples, etc. giving outlying observations. Unless these problems are identified and properly dealt with, they will badly affect the calibration model.

6.1 Deviations of Individual Spectra from the Average

During work with small changes in spectra, it is beneficial to inspect the spectral shapes after subtraction of the mean spectrum. An example is shown in Figures (3a–c) where the diffuse reflectance NIR spectra from three homogeneous metoprolol tablets are shown, first (a) as original spectra, then (b) with the mean from the three tablets subtracted, and finally (c) a spectrum from the pure metoprolol tartrate. From Figure 3(a) it is not possible to see the metoprolol variation. However, in Figure 3(b) the same main patterns are visible as in the pure substance spectrum in Figure 3(c). Also note that the scale in Figure 3(b) covers 0.05 log(1/R) units while the scale in Figure 3(a) covers 0.6 units. This inspection serves well to give a first impression of the main spectral variation. The spectral interpretation aids in the confidence of the method. When the TS is generated according to a design there may be more than one distinct spectral variation. In that case this inspection may be complemented by inspection of the principal components analysis (PCA) spectral loadings as described below. This type of inspection is a good alternative to the use of derivatives as inspection tool. The original shape of the spectral variation is preserved and no information is removed.

6.2 Multivariate Quality Control of the Data by Principal Components Analysis

The correlation structure in multivariate data (here digitized spectra) allows the straightforward identification of outliers by means of PCA. Also “univariate outliers”, deviating strongly in only a single variable, are seen in the PCA, particularly in the RSDs, $s_i$. The same analysis provides indications also about the balance and representativity of the signal matrix, $X$, as well as about the rank of $X$, i.e. the inherent dimensionality (complexity) of $X$. The latter is closely related to the number of detectable constituents in the investigated set of samples.

In the example, a PCA of the training data (centered but unscaled, see section 7.3.4) gives three significant components indicating the presence of three constituents. However, only two components are expected with two analytes. The third, very small component ($R^2 = 1\%$) indicates some kind of deviation from Lambert–Beer behavior. The loading vector of the third component ($p_3$) looks similar to a linear combination of the first two loadings (Figure 4), but the third score vector ($t_3$) does not have any clear relation neither to felodipine, nor to metoprolol (Figure 5b).

6.3 Outliers in X and Unbalanced X-data

The $t_1$, $t_2$ score plot of the TS (Figure 5a) does not show any strongly deviating observations, but displays a pattern corresponding to the concentration design matrix. This indicates that the dominating systematic part of the spectroscopic data is related to the concentrations, $Y$. The RSDs, $s_i$ (section 8.4.2) also are within the normal limits.
Figure 4 The three PC loading vectors (p1 to p3) of ex.1 plotted vs variable number.

The t1, t2 score plot also shows a well balanced TS without any empty regions or strong clusters. This further corroborates the good distribution of the data, and hence these training data sets have passed the first “quality control”.

6.4 Outliers in Y
With many Y-variables, a PCA of Y shows that, analogously to above, the balance of the Y-data, the presence/absence of outliers and clusters, etc. This analysis is relevant when the data has more than four or five y’s. For a partial least-squares multivariate calibration (PLS/MVC) the Y-outliers will also be visible in t vs. u plots for the significant components. If several outliers are present the most deviating will show up first. When these are removed additional milder outliers may show up. A common cause for Y-outliers is that the value from the reference method is wrong.

7 DATA PREPROCESSING
The raw data coming out of the measuring instrument (typically the spectrometer) are not necessarily expressed in the form that is most suitable for the mathematical calibration. Hence there is often a motivation for modifying the raw signals, both by simple transformations such as logarithmic, or by complex modifications such as Fourier transformation, filtering, variable selection, baseline correction, and differentiation.

The preprocessing of the TS and of new samples (the prediction set) should be the same. When the preprocessing contains adjustable parameters, e.g. averages, SDs, orthogonal signal correction (OSC) components, etc. these parameters are based on the TS, and the same parameter values are then used for the new samples.

7.1 Choice of Representation (Time or Frequency Domain)
As discussed in section 3.7, multivariate signal profiles come out of the instruments usually either in the form of
a spectrum (light absorption at different wavelengths or frequencies) or, with a FT spectrometer, as an interferogram (spectral amplitude as a function of mirror distance or time). As humans we usually prefer the first representation, but nothing indicates that either is more useful for MVC. Hence, with FT spectroscopy it may sometimes be preferable to use the digitized interferograms directly as objects, and then back-transform the resulting model coefficient profiles to a spectral representation for the interpretation of the results. Our experience is still not sufficient to provide any guidelines.

7.2 Logarithms and Other Stabilizing Transformations

If the signals are exponentially distributed, taking their logarithms is recommended before the data analysis. This may also stabilize the influence of the noise on the model if the size of the noise is approximately proportional to the concentration. This is common when the latter varies over several magnitude of ten. If the value zero occurs frequently in the signal matrix, the fourth root is an alternative transformation which has a similar “compressing” effect as the logarithm on large values, but it does not inflate very small values, and the fourth root of zero remains zero.

If a linear relation is expected between the original signals (Z) and the concentrations (Y), then both Z and Y should be transformed in the same way. Hence, if log(Z) is used, this implies that also log(Y) should be used in the calibration.

7.3 Spectral Correction Methods

Particularly with diffuse reflectance spectroscopy, there is often a need of a spectral preprocessing to remove baseline variation and other systematic variations in the data that are not related to the analyte concentrations or other properties of interest. Then so-called signal correction methods are applied, or, alternatively, first or second derivatives of the spectra along the wavelength axis are calculated (spectral differentiation). We emphasize that there is presently not sufficient experience with data preprocessing and MVC to select the appropriate approach a priori, and a comparison between the results of different approaches including the use of unmodified data should always be made.

7.3.1 Additive and Multiplicative Signal Corrections

Large interfering additive and multiplicative variations are often present in spectra along with the desired information. The additive effects are visible in spectra as offsets. The multiplicative effects are visible as a scaling factor where proportions between spectral peaks are preserved while the spectral magnitude varies.

It is possible to include these variations in the MVC, but at the cost of an increased complexity of the calibration model. With principal components regression (PCR) and partial least-squares regression (PLSR) several extra components may be needed. This often affects the predictive precision negatively, and also makes the model interpretation more difficult.

This type of variation is common with diffuse reflectance methods, since the effective cell path is not exactly defined, as in transmission spectrometry. In NIR diffuse reflectance the cell path variations will cause multiplicative effects and e.g. a smaller particle size will give a lower baseline of a log(1/R) spectrum, i.e. the spectrum will appear “lighter” for the spectrophotometer.

In diffuse reflectance NIR spectrometry these effects are often the most dominating, which means that they are modeled in the first component if PCR or PLSR is used. When the objective is to model chemical properties with a simple MVC model, the corrections can be used. As a consequence of the simple model, the scores and loadings will in many cases be easier to interpret. The correction will, however, not cure bad data.

In cases when the MVC is aimed at physical properties such as particle size, no correction should usually be made, however. This because these physical properties may be reflected in light scatter, etc. i.e. components little related to concentration. As an alternative, the sizes of the additive and multiplicative corrections may be added as two appropriately scaled extra variables in the calibration. (1)

Multiplicative signal correction (MSC), or mean centering of the objects followed by a scaling of each row to unit SD, are two variants of the same correction except for a scaling factor. (23,24) The object centering and auto-scaling has also been named the standard normal variate (SNV) transform. (25) Both transforms remove the additive and multiplicative effects. Spectra may also be detrended by fitting and subtraction of a low order polynomial. Dhanoa et al. recommends that this should be done before the SNV correction. (24)

The MSC algorithm uses univariate linear regression with a plot of the TS mean spectrum against each individual spectrum. The resulting intercept is used for the additive correction and the slope is used as the multiplicative correction of each spectrum in the TS. Further measured samples, in the test and prediction sets, have to be corrected with the saved TS mean spectrum.

Denoting the row vector of the average spectrum of the TS by m, each training and prediction set observation row vector, z_i, is corrected as follows. First the slope, a_i, and the intercept b_i, are calculated by least squares (ε is a residual vector), Equation (7):

\[ z_i = a_i + b_i m + \varepsilon \]  

(7)
Then, the “corrected” vector, \( x_i \), is calculated as Equation (8):

\[
x_i = \frac{z_i - a_i}{b_i}
\]

The relation to a mean spectrum is a disadvantage with MSC since the mean spectrum has to be recalculated for each selected TS. That is avoided with SNV.

The MSC has been applied both to the entire spectral range present in the MVC and to parts thereof. One way to correct measured variables that contains an internal standard, would be to correct the whole spectrum with an MSC that get its slope and intercept only at the variable interval where an internal standard is present.\(^{(1)}\)

### 7.3.2 Optimal Scaling

Optimal scaling is preprocessing that corrects for the nonlinearity created when spectra are normalized before the calibration.\(^{(26)}\) Optimal scaling can also correct for multiplicative effects. This is done by the addition of a multiplier \( m_i \) for each sample in \( Y \). Then Equation (9) will be complemented by a diagonal multiplier matrix \( M \):

\[
MY = XB + F
\]

The MVC is then constituted as a solution to Equation (9) including the optimized \( m_i; s \). The regression coefficients \( B \) may be solved as

\[
B = X^+MY
\]

where \( X^+ \) is the generalized inverse of \( X^T X \) for the cases when \( X \) is singular.

Optimal scaling improves PLS calibration on normalized X-ray diffraction spectra.\(^{(26)}\) This scaling is, however, not appropriate for the correction of additive effects. Raw data with additive anomalies should be corrected with another method before the application of optimal scaling.

### 7.3.3 Orthogonal Signal Correction

OSC\(^{(27,28)}\) is a recently published correction method. The main idea is to remove systematic variation in the \( X \)-variables that is not correlated to the variation in the \( y \)-variables. This is another way to remove variations introduced by variations in the apparent cell pathlength. In contrast to the MSC and SNV, OSC needs the \( y \)-variable to guide the correction. It is also possible to use OSC to reduce the size of interferences such as the switch of instruments.\(^{(28,29)}\)

The OSC operates as a reversed PLS calibration. A multivariate model of the TS is built, but the objective of the model is to describe variations that are orthogonal to the \( Y \)-variable(s). The model is composed of OSC-components, just as a PLS-model is composed of PLS-components, (Equation 11):

\[
X = T_{osc}P'_{osc} + E
\]

The residual matrix \( E \) contains the OSC-filtered data, which are thereafter used as the TS signal matrix in the MVC. Just like ordinary PLS, OSC also gives a weight matrix, \( W_{osc} \) such that (Equation 12):

\[
T_{osc} = XW_{osc}^*
\]

Spectra of new samples (centered and scaled) are then filtered using the same OSC model before they are entered the calibration model to predict the values of \( Y \) (the concentrations). First their “OSC-score” values are calculated, Equation (13):

\[
t'_{osc} = x'_{new}W_{osc}^*
\]

and thereafter the “filtered” values are calculated as Equation (14):

\[
x'_{new, filtered} = x'_{new} - t'_{osc}P_{osc}
\]

The limited experience is that one or two OSC components usually are adequate. The score plots of both the OSC model and of the final PLS/MVC should be used as diagnostic tools. When the score-pattern that is being corrected for disappears from the final MVC, no further OSC components should be used. As always with a multivariate modelling, the OSC may give overfitting if too many components are used.

### 7.3.4 Centering and Scaling

After transformations (log, etc.), the variables are usually centered by subtracting the average values \( (a_k; see below) \) from each column in \( X \) and \( Y \). Thereafter, one can optionally scale the variables by multiplying each by a scaling weight, \( v_k \) or \( v_m \). The most common is to scale both the \( X \) and \( Y \) variables to unit variance. This is done by calculating the column averages \( (a_k) \) and column SDs \( (s_k) \), and then make the linear transformation, Equation (15):

\[
x_{ik} = \frac{z_{ik} - a_k}{s_k}
\]

This corresponds to using the inverse SDs as scaling weights (i.e. \( v_k = 1/s_k \)). The result is that each variable gets the same initial importance in the calculation of the calibration model.

When the variables comprise digitized spectra and all the variables are in the same unit, another common “scaling” is to keep the spectrum as it is, except for centering. With a projection method such as PCR and
PLSR this means that the variables get the importance for the calibration proportional to their variation. Variables should still be centered, and it is the variation after centering that gives the weight (see Figure 3b). This is sometimes a good approach for spectra if large sections of spectra are only reflecting baseline noise. If scaling to unit variance is applied to such data, it will magnify the amount of noise that is entered into the calibration model. However, sometimes the variations in the baseline may be significant for the analysis. This may occur with e.g. fluorescence in Raman spectrometry and in gradient LC. A compromise is to weight the variables proportionally to the inverse of the square root of their SD, often called Pareto scaling. Thus the large variations are still dominating, but the small variations are not scaled down as much.

When blocks of variables give less than optimal response for the instrument type, but these blocks still contain information that is important for the calibration, an option is to down-weight these blocks. This will enhance the detection of aberrant measurements and the calibration performance may increase.

When the \( X \)-variables comprise combinations of spectra from several analytical instruments, the blocks of variables from the different instruments may be combined with weights that let the instruments have “equal votes” in the calibration (block scaling).

It may be also possible to automatically optimize the individual variable weights in a calibration. This is in general not a good practice, since the risk of over-fitting will increase. This method is related to variable selection methods where a large set of selections are tried and the “best” is chosen. This greatly increases the risk of producing spurious correlations.

7.3.5 First and Second Derivatives

When the \( x \)-variables for an MVC have the same unit and are arranged as a continuous function (e.g. in spectra), the first or second derivatives may replace the original variables as \( X \)-variables for the MVC. Using first derivatives removes the linear slope of the baseline and changes all peak maxima to zero-crossings. Using second derivatives reduces the background further and leaves narrower negative peaks at the original peak positions. However, the differentiation also removes all variation in the variables that is not carried by differences between adjacent variables. In the rare case where the majority of the variation in the \( X \)-variables remains after the differentiation, this may be a good pretreatment.

Differentiation removes a sizable amount of variation that may be important for the calibration. Noise will then be a larger proportion of the signal, and will be more visible in spectra. This has made it possible for most derivatives in instrument software to be calculated with smoothing, for instance using Savitsky–Golay approach,\(^{(30)}\) or by subsequent differences between moving averages.\(^{(31)}\)

Care should be taken not to smooth away information. When digital spectra are collected, there is often a digital over-sampling in relation to the bandwidth of the spectrometer. A good rule of thumb is to keep the smoothing parameters in a range that is not degrading the efficient bandwidth of the instrument significantly.

A common misuse of derivatives to use it as a replacement for mean-centering of the variables. MVC models with and without differentiated \( X \)-variables should always be calculated with mean centered \( X \)-variables before comparison.

8 THE ANALYSIS OF THE TRAINING SET DATA; THE CALIBRATION MODEL DEVELOPMENT

With many spectral variables (more than one), a computerized analysis is necessary to use the data efficiently. The basis for this analysis is to develop a model, a mathematical description, of the relationship between the raw or preprocessed spectral variables (\( Z \) or \( X \)) and the concentrations (\( Y \)). There are two basic approaches to this data analysis, multiple linear regression (MLR), or a multivariate projection. The most commonly used projection methods are PCR and PLSR.

8.1 The Mathematical Formulation of Multivariate Calibration

The general form of the calibration model can be derived from Lambert–Beer’s law, which states that at any wavelength the light absorption is linearly related to the concentrations of constituents that absorb at that wavelength.

Hence, according to Lambert–Beer’s law, spectral data \( z_{ik} \)—the spectral absorbance of sample \( i \) at the \( k \)th wavelength—is a sum of contributions from chemical constituents with the concentrations \( c_{im} \) and the spectral unit absorbance \( d_{km} \), plus noise, \( e_{ik} \) (Equation 16):

\[
z_{ik} = \sum_{m} c_{im} d_{km} + e_{ik}
\]  

(16)

In matrix form, this is Equation (17):

\[
Z = CD' + E
\]  

(17)

After monotonic transformations, centering, scaling, and preprocessing (section 7), giving the signal data matrix \( X \), this matrix is still decomposable in the same
way (the resulting residual matrix, $E$, is not the same as above, however), Equation (18):

$$X = TP' + E \quad (18)$$

An important conclusion is that the signal matrix $X$ can be modeled by this PC-like model, also called a bilinear model.

The data analytical problem is now basically to find the parameter matrices $T$ and $P'$ which are related to the concentrations of the analytes of interest. There are several complications, however. First, the number of constituents in a complicated sample is often large, meaning that the rank of $T$ and $P$ is potentially large. Second, there is a rotation problem, which makes $T$ and $P$ nonunique. Inserting any nonsingular matrix $R$ and its inverse $R^{-1}$ between $T$ and $P'$ in Equation (18) gives Equation (19) (remembering that $R^{-1}R = I$):

$$X = TP' + E = TR^{-1}RP' + E = VQ' + E \quad (19)$$

Finally, the presence of the noise, $E$, presents further problems. The rank of $X$ cannot be determined with full certainty, and any parameter estimation based on $X$ will also result in noise in the parameters.

Hence it is not sufficient to just decompose $X$ by PCA because the resulting score matrix $T$ cannot be identified with the desired analyte concentrations $Y$. Instead one has to find a way to find the loadings $P$ so that at least the resulting scores ($T = XP$) are linearly related to the concentrations $Y$ (PCR and PLSR, below) by coefficients $Q$. Equation (20):

$$Y = TQ' + F \quad (20)$$

Equation (17) can be multiplied from the right with $D^{-1}$, giving Equation (21), after rearrangement:

$$C(\text{or } Y) = ZD^{-1} + F = ZB + F \quad (21)$$

Hence, we can, in principle, find coefficients $B$ that directly relate the signal matrix to the concentrations by a MLR model (Equation 5). This might seem more attractive than going via the bilinear decomposition of $X$, but actually leads to a loss of information since no modelling is made of the signal matrix $X$ and its correlation structure. This information loss makes both the interpretation of the model and the recognition of anomalous samples model difficult. Also, usually the variables in $X$ are strongly correlated, which makes the MLR solution impossible to compute without an extensive variable reduction. This can be made in simple cases, but is difficult with complicated samples without distinct spectral regions. The different approaches – PCR, PLSR, and MLR – are discussed below (section 8.4).

### 8.2 Linear or Nonlinear Calibration Model

Relationships between measured data are, in principle, nonlinear. However, over limited intervals these relationships are usually very close to linear, and can hence be adequately approximated by a linear model. However, if the relationship appears to be curved, the linear models can easily be extended to quadratic or cubic models, handling polynomial (mild) nonlinearities (section 8.4). These nonlinear models work as long as there is a monotonic relationship between signals ($X$) and concentrations ($Y$), i.e. the spectral variables always increase (or decrease) when the concentrations or other calibration properties increase in value. Stronger nonlinearities are impossible to deal with even in principle, since then the calibration model becomes noninvertable and a given signal profile will correspond to several different concentrations.

#### 8.3 One or Several Analytes

With several analytes and a multivariate $Y$-matrix of concentrations, there are two principally different ways to perform the MVC. Either one can develop a separate model for each analyte, or one can develop a single model for all analytes. Each approach has its merits. The separate models are often easier to understand and use, and often give slightly better predictions, especially if the $y$-variables are close to orthogonal. This situation typically arises when calibration samples are prepared from pure substances and their mixtures varied according to a statistical design as discussed in section 3.2 above.

The multi-analyte model is preferable when the number of analytes is large and the concentrations (or other properties used as $Y$) are correlated. This is typical for noncontrolled samples of natural origin, i.e. the second case discussed in section 3.2. Then the simplification of a single model is strongly desirable, and possible small gains in predictive precision in one or a few of the analytes by using separate calibration models are offset by the ensuing increase in complexity of developing and maintaining a large number of different calibration models.

With noncontrolled samples, it often happens that the analytes are correlated groupwise. This grouping is usually seen in the loading plots of a PCA of the concentration matrix, $Y$. Making a separate model for each group of correlated analytes is then a natural approach.

### 8.4 The Calibration Model

The choice of the calibration model depends mainly on the complexity of the calibration problem and the corresponding data structure. One of the great advantages
with projection methods is that they can handle data sets with very many and correlated X-variables, even many more than the number of calibration samples, N. For such data, the ordinary MLR cannot even be computed. With many X-variables, K, and most of them containing information about Y, projection methods are hence the choice, while for very simple problems where a few wavelengths can be selected to give an adequate calibration model, MLR is often used. As indicated in the end of section 8.1, however, projection methods may still be preferable also in simpler problems, because they give additional information beyond the results of MLR.

8.4.1 Projection Methods

As discussed in section 8.1, we expect that the signal matrix X can be decomposed as a product of a matrix T (the score matrix) and a matrix P′ (the loading matrix), Equation (18). Moreover, the scores (the columns of T) can be used as predictor variables of the concentrations, Y (Equation 20). This is the basis for the two most commonly used MVC models, namely PCR and PLSR.

The former PCR is based on first making a PCA of the signal matrix X according to Equation (18), and then developing a second model of the relation between the score matrix (T) and the concentration matrix Y (Equation 20). Each PC consists of one score vector (t_a) and one loading vector (p_a), and the component index (a) runs between one and A (the number of components of the model). The components, i.e. the columns of T and P, are mutually orthogonal, and the latter (the P columns) are normalized to length one. Moreover, the score vectors (t_a, i.e. the columns of T) are sorted in order of the importance for X, i.e. t_Ap describes more of X (its sum of squares (SS)) than does t_Bp, etc. The PC loadings (p_a) and score vectors (t_a) are eigenvectors to the variance covariance matrix (XX) and the association matrix (X'X'), respectively.

Due to the orthonormality of the PCA loading matrix P, and the orthogonality between P′ and the residual matrix E, Equation (18) multiplied from the right by P′ gives Equation (22):

\[ T = XP' \]

For an additional sample (in the prediction set) with the preprocessed data vector X′_new, the predicted PC score values are calculated from this relation, which when inserted in the calibration model (Equation 20) gives the predicted values of Y, Equations (23) and (24):

\[ t_{new} = X'_{new}P \]

\[ y'_{new} = X'_{new}PO' \]

Standard errors (serr_y) and confidence intervals (approximately 2 or 3 times the standard errors, according to the t-distribution) can be calculated in many ways for the predicted y-values, the simplest being based on the regression formalism and the fairly accurate assumption of a fixed (exact) X-score matrix, T. The square of the standard error (error variance) including the variability of the new measure y-values, and assuming a variance of the measurement errors of σ², is Equation (25).

\[ serr_y = \left(1 + \frac{1}{N} + \frac{x'_{new}(T'T)^{-1}x_{new}}{\sigma^2} \right)^{1/2} \]  

(25)

PCR presents some complications, however. In particular in complicated samples, there is often a strong systematic variation in X that is not related to Y. Also, especially in reflectance spectroscopy, there is often a baseline variation and a multiplicative effect due to light scatter and varying light path length. This makes the first few PCs little related to Y, with the ensuing loss of information. This may be remedied by appropriate data preprocessing (section 7). However, the fact that the components of X are derived without using the information in Y, makes PCR often need many components to capture the parts of X that are relevant to Y, with a resulting loss of predictive precision.

PLS projection to latent structure PLS is a method where the projection of X is made to enhance the information content about Y in the score matrix, T. This decreases the risk for losing information about Y in the projection of X, and with complicated samples PLSR usually needs fewer components than PCR to achieve the same explanation of Y. With very calibration samples and many X-variables, this is often an advantage, and PLS usually gives a smaller prediction error than PCR. In many applications, however, where the information in X about Y sits in the first few components like in the present example, the differences are miniscule and chemically and statistically insignificant.

The PLS model is developed with two objectives, namely to model X, and to predict (model) Y from X. The former is accomplished by finding new “variables”, the scores (t_a), that well summarize X, and the latter objective is achieved by focusing the projection on the parts of X that are related to Y.

The PLSR model has identical form as the PCR model (Equations 18 to 20), but the actual values of the parameters (T and P) are different, as well as the dimensionality (A). The computation of the PLS parameters is made in such a way that the PLS score matrix, T, is an optimal compromise between modelling X and predicting Y. This compromise is sometimes called the “H-principle” which points to the analogy with Heisenberg’s principle of uncertainty. This is achieved by having the first PLS score vector (t_1) be the largest
eigenvector of the extended association matrix, \( XX'Y Y' \) in contrast to the first PC score vector which is the largest eigenvector to just \( XX' \). The subsequent PLS score vectors \( (t_i) \) are eigenvectors of \( E_{a-1} E_{a-1} \ Y Y' \), where \( E_{a-1} \) is the matrix of X-residuals \( (X - T_{a-1} P_{a-1}) \) after \( a-1 \) components. The PLS model of \( Y \) is formulated as a linear model between the X-scores and the Y-variables, with a coefficient matrix \( C \), Equation (26):

\[
Y = TC' + F = XW'C' + F = XB + F
\]  

(26)

In PLS there is a second matrix of “loading vectors”, denoted by \( W \), with one column per PLS component. A variant of \( W \) denoted by \( W^* \) contains the weights that directly combine the X-variables to form the scores, \( t_i \). Thus, analogously to Equation (22) we obtain Equations (27) and (28):

\[
t_i = Xw_i^*
\]  

(27)

\[
T = XW^*
\]  

(28)

This is used for calculating the predicted values of \( Y \) for new samples with X-data \( x_{\text{new}}' \) according to Equation (29):

\[
y_{\text{new}}' = x_{\text{new}}' W^* C'
\]  

(29)

The standard errors and confidence intervals for these predicted values are calculated in the same way as for PCR, i.e. by Equation (25).

### 8.4.2 Diagnostics Common to Both Regression Methods

The diagnostics and the interpretation of PLSR is the same as for PCR, as well as the way to calculate predicted y-values (e.g. concentrations) for new samples. The only difference is that in PCR, the X-scores for new samples are calculated by means of the loadings, \( P \), while in PLS, these scores are calculated by means of the weight matrix \( W^* \) (Equations 22 and 28 respectively). We note that the X-residuals are calculated in the same way for both PCR and PLS (from Equation 18) by Equation (30):

\[
E = X - TP'
\]  

(30)

The X-residuals, \( E \), express the deviations between the data \( X \) and the model \( (TP') \). For new observations (samples), the X-residuals \( (e_{\text{new}}') \) are calculated in the same way as the preprocessed sample x-vector minus the calculated scores times the loading matrix of the model, Equation (31):

\[
e_{\text{new}}' = x_{\text{new}}' - t_{\text{new}} P'
\]  

(31)

A great advantage of projection methods is that data of new samples in the prediction set can be “quality controlled” by inspection of their RSD values \( (s_{\text{new}}) \) (Equation 32). The RSD of observation \( i \) shows how far this observation is from the model, however dissimilar it is to the model.

\[
s_{\text{new}} = \frac{e_{\text{new}}'}{K - A}
\]  

(32)

If the value of this RSD for a new sample is larger than a certain limit \( (d) \), the sample is an outlier not being similar to the TS. This, in turn, indicates that the predictions of the concentrations \( y \) are unreliable for the sample. The limit \( (d) \) for the RSD is calculated from the RSD of the whole training matrix \( (s_0) \) and a critical value of the F-distribution (Equations 33 and 34).

\[
s_0 = \sqrt{\sum_{i} \sum_{k} \frac{e_{ik}^2}{(N - A - 1)(K - A)}}
\]  

(33)

\[
d = s_0 \times \sqrt{F_{\text{crit}}}
\]  

(34)

#### 8.4.3 The Number of Model Components \( A \)

The number of components used in the PCA of \( X \) \( (A) \) is determined either by cross-validation (CV), or by using components with eigenvalues significantly larger than some limit, usually between 1.0 and 2.0. The eigenvalue of a component is the fraction of the SS of the signal matrix \( X \) that is explained by the component, multiplied by the number of variables \( (K) \). A component with an eigenvalue larger than one explains the worth of at least one variable. One further alternative (not recommended) is to sufficiently use many components to make the SS of the residuals \( E \) smaller than a fraction of the SS of the signal matrix \( X \).

With CV one estimates the number of components \( A \) by dividing the elements in the data matrix \( X \) in a number of groups, usually seven or nine. One then makes a number of separate analyses, each time keeping out one of the groups of the data (setting them as “missing”). The model is then used to predict the deleted data, and the ensuing prediction errors (predicted value minus actual values) are calculated. The resulting SS of these prediction errors is called predictive residuals sum of squares (PRESS), and one selects the model dimensionality \( A \), which gives the smallest PRESS. This approach is called full CV. Alternatively, one calculates one PC after another with a renewed CV for each component, until PRESS stops to decrease in size, so-called partial CV. Full and partial CV usually indicate the same number of components or very close.

Like with PCR, the number of significant PLS components is determined by CV. Since there is a \( Y \)-matrix in PLS, the CV of PLSR is different from that of PCA, and the PRESS relates to the predictive residuals of the \( Y \)-matrix. In CV of PLS, the deleted groups of data contain...
whole objects (\(X\) and \(Y\)-data). A PLS model is developed without this group, and the predicted \(Y\)-values are then calculated for the deleted objects. These \(Y\)-values are compared with the actual values, and PRESS equals the SS of the difference between observed and predicted \(Y\), the predictive residuals. Hence the CV in PLS relates directly to the objective of predicting \(Y\), while the CV of PCA tells us only about the significant structure of \(X\). Also for PLS, CV can be made in a full or partial way, giving similar results in most practical cases.

8.4.4 Computational Algorithms for Both Regression Methods

PCA is mathematically equivalent to singular value decomposition (SVD) as it is usually called in numerical analysis and computation science, and to principal factor analysis, Karhunen-Loève decomposition, and eigenvector analysis as this is often called in physics and engineering. Hence, PCR starts with a PCA of \(X\), followed by a simple MLR using the first few PC score vectors, \(t_k\), and predictor variables.

Many different algorithms exist for the calculation of the principal components parameters, where, historically, the first were based on the diagonalization of the variance covariance matrix \(XX'\). The resulting eigenvectors equal the loadings, \(p_k\). Today, however, the most commonly used algorithms are based on SVD,\(^{37}\) or on the NIPALS method.\(^{38}\) The latter is very fast if just a few PCs are needed, and also works for incomplete data matrices.

Like for PCR, many algorithms exist for calculating the PLS parameters. The most common is based on the NIPALS algorithm\(^{39}\) which has the advantage of also operating with incomplete \(X\) and \(Y\) matrices, and to extract only as many components as actually are needed in the model. Other algorithms are based on the calculation of eigenvectors of the matrices \(XX'YY'\) or \(XYYX\).\(^{40–42}\)

These two matrices have the dimensions \((n \times n)\) and \((K \times K)\). The first is small for few samples, and hence advantageous for fast computations.

8.4.5 The Example

In the example, a PCA of the first 10 samples (the TS) gives three components as shown above in section 6. The two PCR calibration models for \(y_1 =\) felodipine and \(y_2 =\) metoprolol based on the corresponding score vectors explain the two \(Y\)-variables well \((R^2 = 0.9996\) and 0.9991, and \(Q^2 = 0.9817\) and 0.9153 respectively). The fitted and predicted values for the second model are shown in Figure 6, as well as in Table 1.

8.4.6 Multiple Linear Regression

The first method used in MVC was MLR used with a small selected subset of variables. These variables are usually selected by inspecting spectra of fairly pure constituents. The number of variables should be at least two per constituent, i.e. four in the example. In the absence of impurities, the 4 wavelengths 11, 2, 39, and 57 seem like a good selection in this example. A number of automatic variable selection procedures exist for MLR, but the experience shows that a selection based on chemical and spectroscopic knowledge is preferable. In the case where such knowledge is weak or absent, full spectrum methods such as PCR and PLSR should be used at least as starting points to identify important regions in the spectrum.

MLR starts directly with the model in the form of Equation (5). The coefficients \(B\) that minimize the SS of the residuals in \(F\) are given by Equation (35):

\[
B = (X'X)^{-1}X'Y
\]  

(35)

Predicted values of \(Y\) for new samples are obtained as Equation (36):

\[
y'_\text{new} = x'_\text{new}B
\]  

(36)

The standard errors and ensuing confidence intervals are given in Equation (37) which is analogous to Equation (25), but with \(X\) instead of \(T\), because in MLR all
X-variables are assumed to be independent:

\[ \text{serr}_{y} = \left( 1 + \frac{1}{N} + x_{\text{new}}^{T}(X^{T}X)^{-1}x_{\text{new}} \right) \sigma^2 \]  

(37)

9 METHOD PERFORMANCE AND VALIDATION

The use of analytical method validation is crucial for the operation of many regulated businesses such as the pharmaceutical industry, and for quality-rated analytical laboratories. Method validation is an activity that is meant to prove that an analytical method is indeed doing what it is supposed to do. The requirements on the analytical method should correspond to the needs of the operation. For process analysis, speed of analysis may be more important than the lowest possible error in each analysis. When product bulk properties are measured, other requirements are more important than when environmental trace analysis is performed. This means that the first step in method validation is to determine what we want and what requirements that will lead to.

The validation is usually broken down into a set of performance measures such as selectivity, sensitivity, limit of detection, linearity or model fit, repeatability, reproducibility, accuracy and robustness. The possible lowest limits for these performance measures vary with the analytical method. The validation task for an MVC is often to prove that the MVC performs on the same level as the reference method. It is important to notice that the model is not the method. The analytical method has to be a description of the development of calibration models.

9.1 Measures of Model Performance

Today the pharmaceutical industry has a well regulated set of performance measures that has to be reported for an analytical method. Hence these can be used as a framework for MVC. A set of performance measures in pharmaceutical analytical method validation mainly taken from the suggestion list of the International Harmonization Committee (IHC) (International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use IHC secretariat c/o IFPMA, 30 rue de St-Jean, PO Box 9, CH-1211 Geneva 18, Switzerland.)\(^{(43)}\) will be covered. These measures are mostly developed with UVCs in mind. Their application for MVC will be discussed.

The calibration model can be evaluated according to very many criteria. According to our present knowledge of analytical chemistry, the following set of criteria cover most practical needs.

9.2 Selectivity

The selectivity of an analytical method is defined as the extent to which it can determine particular analytes in a complex mixture without interference from other components in the mixture.

MVC is able to make a selective analysis by the use of mathematics. The requirements for this to work is that the other compounds in a mixture have different magnitude relations for the same spectral variables and that the amounts of the interfering compounds are varied in the TS independently of the analyte amount. This can be tested by the variation of physical properties, matrix components, and interfering compounds to samples in the test set. Then the selectivity as a deviation in the analytical result can be estimated as \(Q_{\text{test}}\) for this test set, by Equation (38):

\[ Q_{\text{test}} = 1 - \frac{S_{F,\text{test}}^2}{S_{Y,\text{test}}^2} \]  

(38)

Here \(S_{F,\text{test}}\) is the SD of the y-residual for the selected test set and \(S_{Y,\text{test}}\) is the SD for the total variation in the y-variables.

When the amounts of interfering compounds are outside the scope of the model, the residual error for the x-variables (E) should be large enough to rise beyond a decided limit of acceptance. The verification of the residual diagnostics should be included in the method validation.

Selectivity is related to the concept of “net analyte signal” (NAS) of Lorber et al.\(^{(44)}\) It is claimed that NAS can be used as a basis for a broad range of MVA diagnostics. In its present form, however, the NAS estimation needs the pure spectra of the constituents of interest, making NAS work only in simple concentration calibrations. Also, the experience with the NAS concept in MVC is too short to allow an evaluation.

9.3 Accuracy

The accuracy of a method can be defined as the closeness between the analytical result and an accepted reference value, sometimes termed the true value.

The estimation of the accuracy should be applied across the range of the analytical method. Reference materials, or a separate well-characterized procedure with known accuracy, may be used for this purpose. The reference method for the MVC is a valid alternative for the comparison if it is well characterized. A report of the accuracy may include a root mean square error of prediction (RMSEP) for the test set in Equation (39):

\[ \text{RMSEP} = \frac{1}{n} \sum_{i=1}^{n} (y_{i,\text{ref}} - y_{i,\text{pred}})^2 \]  

(39)
where $y_{i, \text{ref}}$ denotes the values obtained from the reference method and $y_{i, \text{pred}}$ the values predicted by the MVC. This may be complemented by an estimate of the average bias between the reference method and the MVC results for the test set, in Equation (40):

$$\text{bias} = \frac{1}{n} \sum_{i=1}^{n} (y_{i, \text{ref}} - y_{i, \text{pred}})$$ (40)

For pharmaceutical-method validation with one $y$-variable, a minimum of nine determinations is recommended by IHC over a minimum of three concentration levels. For the MVC with more than one $y$-variable this may be extended to minimum three levels in each $y$-variable.

### 9.4 Precision

The precision of an analytical method can be defined as the closeness between repeated measurement of subsamples taken from the same homogeneous sample. The sample should be authentic. Three levels of precision measurements are defined by IHC: repeatability, intermediate precision, and reproducibility. The precision is often reported as the variance, SD, or coefficient of variation of a series.

#### 9.4.1 Repeatability

The repeatability expresses the variation during a short interval of time with the same operating conditions. For pharmaceutical use, a minimum is six determinations at a 100% level of the analyte, or nine determinations covering the analytical range.

#### 9.4.2 Intermediate Precision

The intermediate precision should include possible variations within a single laboratory, such as different days, different analysts, and different equipment. It is not necessary to study these effects one by one. For pharmaceutical use, the experimental design approach is encouraged. Then the sizes of e.g. the day, analyst and equipment effects are quantified as coefficients in a regression for evaluation of the experimental design. See section 9.10 below.

#### 9.4.3 Reproducibility

The reproducibility can be defined as a case when both within and between laboratory variations are included in the evaluation of the precision. This involves an inter-laboratory trial. For certain types of MVC, e.g. NIR calibrations, this level of precision involves the topic of calibration transfer or the use of well-accepted standards. As with intermediate precision, the results can be evaluated using an experimental design.

### 9.5 Sensitivity

Sensitivity, or how low are the concentrations that an instrument can detect, can be defined in many ways, where the most common are detection and quantitation limits.

#### 9.5.1 Detection Limit

The detection limit can be defined as the lowest amount of analyte that is still detectable by the method but not necessarily quantifiable with good precision.

The detection limit may be estimated in ways such as visual evaluation, signal-to-noise ratio (S/N) (often 3:1 or 2:1), SD of the blank, a calibration curve on the same level as the detection limit, or an extrapolation of the calibration curve. When extrapolation is used it should be justified with test samples.

The multivariate spectral S/N can be defined (Equation 41) as the net signal ($S_X^2 - S_E^2$) divided by the noise:

$$\text{S/N} = \frac{\sqrt{S_X^2 - S_E^2}}{\sqrt{S_E^2}}$$ (41)

where $S_X$ is the SD of the gross signal i.e. the SD over all measured samples and variables, and $S_E$ is the SD of the noise i.e. the spectral x-residuals.

The MVC detection limit is, however, more directly dependent of the $S_F$ which is the SD of the $y$-residuals. Hence a multivariate detection limit can be estimated as $3S_F$.

For pharmaceutical use this estimation is recommended for nonquantitative limit tests, i.e. classification methods, while the quantitation limit is recommended in use of quantitative calibrations at low analyte levels.

#### 9.5.2 Quantitation Limit

The quantitation limit can be defined as the lowest level of the analyte where the calibration is still working with a suitable accuracy and precision. The same methods as for the detection limit are applicable but a recommended S/N is now increased to 10:1. Analogously the multivariate quantitation limit can be estimated as $10 \cdot S_F$.

For pharmaceutical use, this estimation is recommended for low analyte levels, but it is not necessary if the calibration works in a range well above the low levels for the given analytical method.

### 9.6 Model Fit or Linearity

The linearity of an analytical procedure may be defined as the ability to give results that are proportional to the
analyte concentration in the sample within a given range. This works well with univariate linear regression. For MVC there are additional measures of performance.

The model fit may be based on diagnostics such as percent explained variation, CV, t vs. u score plots, calibration y-residuals vs. y-size, multivariate correlation coefficient, etc.

9.6.1 Degree of Fit

The size of the “leftovers” after modelling, i.e. the residuals, is useful as a measure of how well the model fits the data. This is often re-expressed as the amount of variation explained, and denoted as $R^2$. This can, in projection models, be calculated both for the Y and the X parts of the data, Equations (42) and (43):

$$R_Y^2 = 1 - \frac{S_E^2}{S_Y^2}$$ (42)

$$R_X^2 = 1 - \frac{S_E^2}{S_X^2}$$ (43)

Here the residual variances, $S_E^2$, and $S_Y^2$, as well as the variances of the data, $S_Y^2$ and $S_X^2$, are uncorrected for degrees of freedom, i.e. the sums of squares divided by $N \times M$ and $N \times K$, respectively. If one uses the variance corrected for degrees of freedom, which for the residuals F and E are $(N - A - 1) \times (M - A)$ and $(N - A - 1) \times (K - A)$, respectively, the $R^2$ s are called “adjusted”.

The square roots of these variances, then usually corrected for the degrees of freedom, are called the RSDs, of Y and X, as given above in Equation (33).

9.6.2 Cross-validation

If the predictive residuals from CV (8.4.3) are used instead of the “fitted” residuals in Equations (42) and (43) we get the cross-validated $R^2$ s. These are often denoted by $Q_Y^2$ and $Q_X^2$. Here $Q_Y^2$ is usually the only one of interest, and it is often denoted just by $Q^2$. The corresponding RSD based on predictive residuals is often called SECV (standard error of cross-validation). One should note that the denominator in this is always $N$, since there is no loss of degrees of freedom in the CV process.

9.6.3 Prediction of Validation or Prediction Set

Analogously, if the residuals from a real prediction with a new prediction or test set are available, they can be used to calculate a predictive $Q^2$, denoted by $Q_{pred}^2$, with the corresponding predictive RSD, denoted by SEP (standard error of prediction).

9.7 Range

The range of an analytical method can be defined as the interval between the upper and the lower levels of analyte present in the samples, where the precision, accuracy and model fit are suitable for the analysis.

Since MVC involves the use of a local model, extrapolations will not be accurate. This means that the range will be limited approximately to the range of levels entered in the CS used during method validation. Since samples outside the validated range may occur, it is advisable to include a path for extension of the range in the analytical MVC method together with its validation e.g. using the diagnostic tools for model fit above.

9.8 Robustness

The robustness can be defined as the measure of the ability of the analytical method to remain unaffected by small, but purposely made disturbances in method parameters. These are: measurement errors during sample pretreatment, temperature, humidity, variations in grinding, the stability of analytical solutions, extraction times, influence of chromatographic mobile-phase composition, flow rate, different lots of columns, etc. The evaluation of the robustness indicates the level of reliability of the method. Individual factors that may harm the robustness can be identified and compensated for, if the robustness test is made according to an experimental design.

9.9 System Suitability Testing

The system suitability testing can be made as an integral part of an analytical method. The system suitability test is aimed to make an overall test of the entire function of the analytical equipment used.

During the use of a MVC model for prediction, the RSD from the calibration x-variables is useful as a system suitability test.

9.10 Validating the Calibration Model (Including its Robustness)

The investigation of all points above is very time-consuming unless an experimental design is made taking into factors that may influence the results of the MVC. The ranges of the design factors should be small and correspond to around three times the range of experimental control of these factors. The center of the design should be the conditions specified for the analytical method. Since the variations are small, a reduced design aimed at a linear model for evaluation is expected.

If these design factors include “day of analysis”, “analyst”, “instrument” (equipment), and “laboratory”, the results will be informative both for intermediate
precision and robustness. If the center point of the design is repeated six times the results also indicate the repeatability of the method.

We must remember that this validation (and robustness study) indicates the performance of the whole analytical process, from sample preparation to the stability of the instrument, and that the MVC is just a part of this process. A common and good result from robustness studies will be that none or few factors are affecting the analytical result. This is reflected in the evaluation of the design as no model present or only a few significant factors.

10 CALIBRATION TRANSFER (BETWEEN INSTRUMENTS, LABS, AND OVER TIME)

Calibration transfer is a process where a calibration model developed for one or more instruments is going to be applied to data from additional instruments not included in the primary calibration model. If the variations are large and the instrument is linear, external standards may be applied. This often holds for UV/VIS spectrometry in liquids and LC. In e.g. NIR diffuse reflectance measurements the magnitude range that is actually used is much smaller (see Figure 3b). For these types of cases, a very local calibration in one instrument has to be moved to another instrument. To preserve the accuracy of the analysis, the local magnitude range of the secondary instrument has to be accurately mapped. This is best done with the same type of samples as the ones present in the MVC.

When the calibration samples are stable with time, the most straightforward solution is to build a new calibration for the secondary instrument but with the same samples and reference analysis results.

Another approach that works for e.g. the same brand and type of NIR instruments even with non-stable samples, is to complement a previous PLS-calibration model by adding samples measured with the new instrument. When the calibration for the primary instrument is well developed also for the interfering variations, it may be sufficient with 10–20% of the original number of samples to span the calibration model also for the secondary instrument. This updating scheme will also work for the same instrument over time.

A variation of this is to make deliberate variations of the instrument parameters and develop the MVC for a set of instruments of the same type from the beginning. This is common in the agricultural sector with calibrations for e.g. protein in wheat. It is also common to adjust this type of calibration for bias and slope on the y-side for the individual instruments.

Another approach is to make the instruments as similar as possible. This route has been taken e.g. by Perkin Elmer for an oil analysis NIR spectrometer. Here the optical bandwidth is artificially degraded to a preset level in order to be constant for all instruments. In addition to this, corrections are made to the wavelength scale and the absorbance scale.

When working in diffuse reflectance mode, the blank spectrum is usually defined by a material that has a flat NIR spectrum. This material should be stable with time. Often a PTFE standard is used. Ceramic is another common material. The batch to batch variations in these materials may lead to different zero levels for the obtained spectra. In some cases is sufficient to bias correct all variables in the spectra in such a way that they appear to have been measured with the primary instrument, and then to use the primary calibration model for the adjusted spectra. The relative differences of the zero levels may be established by a set of standards that is measured with both instruments.

Shenk has developed another transfer method. Here the wavelength scale is scaled by a wavelength standard, then the intensity scale is scaled in an univariate way for each wavelength using approximately 30 standards.

Direct standardization (DS) involves the use of a normal MVC with spectra from standards measured on the secondary instrument as x-variables and spectra from the same standards measured with the primary instrument as y-variables. This technique has been shown to work by Hansen.

One problem here is that the random variations in the translated spectra are lost. Thus the variations that result in large residual errors for the primary MVC will be masked in the translation step. To compensate for this, the residual error should be monitored with the MVC for translation.

Piecewise direct standardization (PDS) is another spectrum modifying technique. Adjacent x-variables have to be continuous and correlated, as they are e.g. in spectra or chromatograms. Here the main idea is to correct both for magnitude and wavelength differences at the same time. This is done by measuring a set of transfer standards that are similar to the measured samples. Then a sliding window for calculations is used along with the standards to build a series of PCR or PLS calibration models with the window range in the secondary instrument as x-variables to the window center of the primary instrument as y-variable. The transfer mechanism is then to apply the array of models to translate spectra from e.g. the secondary spectrometer to spectra as measured by the primary spectrometer.

With PDS the transfer models for some variables are likely to perform less well. This is visible as discontinuities in the translated spectra. In many cases these discontinuities are sufficiently small to be ignored but in other cases, certain regions of the spectra may have to be removed. This may occur for grating spectrometers at the
11 SUMMARY AND CONCLUSIONS

MVC is a recently developed approach to use the multidimensional data emerging from spectrometers and other analytical instruments to indirectly estimate properties of interest in chemical, biological, environmental, and other complicated samples. These properties often are concentrations, but, particularly in process analytical chemistry, MVC is often used to calibrate for other qualities such as strength, film thickness, and viscosity. Due to its novelty, the approach is still not fully developed, and interesting research remains regarding both the applicability of MVC in various areas, and the further development of the methodology toolbox. However, MVC is starting to be used extensively in the chemical industry, which is seen in the appearance of introductory books for the industrial analytical chemist.(5)

The idea of using “all” signals instead of one selected frequency or wavelength is simple but powerful. Simple mathematics is used to combine the signals so that the resulting combinations are much more selective, and usually also much more precise, than the original individual signals. Provided that the instrumental data, the signals X, are relevant for the actual measurement problem, and provided that the TS is representative, and the TS Y-values are sufficiently accurate, MVC works very well.

MVC needs a computer for the computations, which is a major reason why this approach was not used before about 1970. Today, when most analytical instruments come integrated with a computer, MVC is the natural choice for most calibrations.

REFERENCES

32. Rel. 2, 327.

Most analytical chemists recognize calibration as the quantitation of analytes by relating the analyte signal and analyte concentration, although it is also possible to obtain information about other characteristics of the sample through calibration. In the calibration process, a number of samples that have known values of the characteristic to be determined, e.g. concentration, are measured. These are reference measurements, and are known as calibration standards. Traditionally, the measurements have consisted of a single number (a univariate or scalar measurement); they are plotted against the known concentration, to generate a “calibration curve”. (An example of a scalar measurement is a pH value or the area under the curve of a chromatographic peak.) When unknown (test) samples are measured under the same experimental conditions as the standards, their concentrations may be found by regressing their measured signals against the standard calibration curve. However, a significant disadvantage of univariate calibration is that a sensor must be fully selective for the analyte of interest, since any interfering species that may be present cannot be detected when measurements are scalar. This has led to the development of “first-order” calibration methods. These techniques use the relationship between an array of measurements (such as a chromatogram or spectrum) and the analyte concentration to develop a calibration model from which analyte concentrations in test samples can be determined. The array of measurements is a vector, and is known as a first-order tensor, while the calibration model is equivalent to the calibration curve. Since first-order calibration uses many measurements per sample to generate a model, rather than just a single measurement as in the univariate case, it has a number of advantages. For example, multianalyte analysis is made possible as long as there is a standard available for each analyte present in a sample, and outlier detection is also feasible. These types of methods have become popular in recent years, and include partial least squares (PLS) and principal component regression (PCR). It makes sense that when more data are available per sample, more information may be extracted, and this is the source of the success of first-order methods. It therefore follows that, if an analyte signal consists of a matrix of data (also known as a second-order tensor), even more advantages exist. [Examples of instruments that produce matrices of data for each sample analyzed include liquid chromatography/ultraviolet detection (LC/UV) and gas chromatography/mass spectrometry (GC/MS).] This situation allows powerful calibration techniques, known as second-order methods, to be used. The primary advantage of these methods is known as the “second-order advantage”; it allows analytes to be quantitated even in the presence of unmodeled interferents. In other words, the calibration standards do not have to contain any information about the interfering species in the sample. This is of particular value in situations where complex samples are being analyzed, as they do not have to be fully characterized for quantitation of a single analyte. The disadvantage of these methods, however, is their complexity: there are often decisions to be made, such as the values to assign to various parameters, and each method has analysis situations which are more favorable than others. The most common second-order analysis methods are alternating least-squares (ALS) methods, such as parallel factor analysis (PARAFAC) and multivariate curve resolution (MCR), and eigenvalue–eigenvector based methods, such as the generalized rank annihilation method (GRAM) and direct trilinear decomposition (DTD).

1 INTRODUCTION

Calibration is the mathematical and statistical process of extracting information, usually analyte concentration, from an instrument signal. The analytical instruments can be classified according to the tensor order of the data they are capable of acquiring. A single sensor (e.g. ion-selective electrode) generates a single number,
a scalar or zero-order tensor, per sample. Calibration of zero-order data requires the use of univariate methods, where a calibration curve is generated by plotting standard concentrations versus the instrument response. However, the sensor must be fully selective, since if an interferent is present it cannot be detected. An array of sensors, or a spectrometer, generates an array of measurements, a vector or first-order tensor, per sample. In this case, the existence of many measurements per sample makes multivariate analysis and outlier detection possible. Interferents are not a problem as long as they are included in the calibration design. The calibration methods that are suited to this type of data include PLS and PCR, which have become common analysis tools in today’s laboratories.

Recent years have seen the increased use of analytical instruments that produce so-called multiway data, classed as having a tensor order of two (a matrix) or higher. “Multiway” data consist of at least a matrix of numbers per sample analyzed. Powerful calibration methods exist specifically for the analysis of such data, and these methods produce the so-called “second-order advantage”. This advantage allows analytes to be quantified even in the presence of unknown interferents, along with the resolution of the analyte signal in each order. Another advantage of higher-order tensor analysis is the possibility of automatic correction of instrument malfunction and/or drift or baseline changes.

When a matrix of data is produced per sample, the data are known as “second-order” data, because it is produced by a second-order instrument. Some examples of techniques which produce second-order data are the GC/MS, liquid chromatography/mass spectrometry (LC/MS), tandem mass spectrometry (MS/MS) and LC/UV. Fluorescence excitation/emission is also an example of such an instrument. Figure 1(a) and (b) show the three-dimensional image of a sample that was measured by comprehensive two-dimensional gas chromatography (GC×GC).

When multiple samples are analyzed simultaneously, the matrices are combined to form a block of data, often referred to as a three-way data set. For LC/MS data, use of a second-order calibration method would result in the resolution of the chromatographic profile for each analyte, along with the appropriate mass spectrum. With knowledge of the analyte concentrations in the calibration sample, their quantitation in the unknown samples is also possible.

Instruments also exist that produce even higher order data, although they are less common. Liquid chromatography/tandem mass spectrometry (LC/MS/MS) is an example of the type of data one might obtain from such an instrument. The resulting data from this instrument are in the form of a block of data per sample, creating a third-order tensor, and therefore a collection of samples analyzed together will produce a fourth-order tensor. Some of the same calibration methods can be used to analyze both second- and higher-order data. The methods used, however, depend on the underlying structure of the data.

A second-order data matrix may be classed as bilinear or nonbilinear. Data can be described as being bilinear if the pseudo-rank of the matrix (i.e. rank in the absence of noise) equals the number of chemical components in the sample. This type of data results when one order modulates the other, such as in techniques that combine separation with spectrometry. In GC/MS data, for example, the mass spectrum of an analyte will not change as it elutes except in magnitude. Equation (1) represents the nth analyte in a bilinear matrix:

\[ M_{b,n} = x_n c_n y_n^T + E \]
where $M_{b,n}$ is the bilinear data matrix for the $n$th analyte, $x$ is the analyte profile in the first-order (e.g. pure elution profile), $y$ is the analyte profile in the second-order (e.g. pure spectrum), $c$ is the concentration of the analyte and $E$ represents the unmodeled error. The superscript $T$ represents the transpose operator. A mixture of chemical components is therefore represented by Equation (2):

$$M_b = \sum_{n=1}^{N} M_{b,n} + E = \sum_{n=1}^{N} x_n c_n y_n^T$$

where $N$ is the number of chemical components present in the mixture. The decomposition of a bilinear data matrix is depicted in Figure 2.

Nonbilinear data, on the other hand, may be represented by $M_{nb}$ (Equation 3):

$$M_{nb} = \sum_{p=1}^{P} q_p r_p s_p^T + E$$

which describes a matrix that contains a single pure component,$^{(6)}$ where $P$ is the rank of $M_{nb}$, $(q, s)$ is a set of vectors which span the column and row spaces of $M_{nb}$ and each $r$ is a scaling factor that normalizes the corresponding $(q, s)$ vectors. In other words, a pure component response has a pseudo-rank >1 when the data are nonbilinear.

The reason for this difference lies in the way the data are constructed; for bilinear data, one order modulates the other, whereas nonbilinear data do not have this characteristic. In the case of MS/MS data, the mass spectra in the second-order change independently over the mass to charge (m/z) range of the first-order. Consequently, there is no correlation between the mass spectrum at m/z $i$ (in the first-order) and the mass spectrum at m/z $i + 1$, so that a pure component cannot be represented by the outer product of two mass spectra.

The different characteristics of bilinear and nonbilinear data call for different calibration methods. There have been some relatively successful attempts to develop calibration methods for nonbilinear data, such as the nonbilinear rank annihilation method (NBRA) which is based on an eigenvalue decomposition.$^{(6)}$ However, analysis methods are far more common for bilinear data, for a number of reasons. First, bilinear data are more commonly produced by instruments in analytical chemistry, particularly through the combination of separation and spectrometric techniques such as LC/UV. Second, the bilinear model is more amenable to mathematical solutions using linear models.

Bilinear data analysis methods can calibrate for analytes with as few as two response matrices, where one is acquired from a standard sample with known analyte concentrations. Of course, owing to the second-order advantage that has been previously mentioned, either the standard or the sample may contain unknown interferents without adversely affecting the calibration. The particular method that operates on two matrices is named the GRAM, and is based on an eigenvalue–eigenvector decomposition.$^{(4)}$

In cases where multiple standards and/or multiple test samples of second-order bilinear data are available, blocks of data, or data cubes, can be created. This is commonly referred to as three-way data, and the calibration methods that are utilized may be termed either second-order methods or three-way methods. These techniques decompose the blocks into three “ways”, where one way corresponds to the sample concentration information. This allows calibration when a standard is available as part of the data set. One such method is an iterative procedure known as PARAFAC, which was developed in the discipline of psychometrics in the early 1970s for decomposition of three-way data.$^{(7)}$ This method uses alternating least squares, and is suitable for data that have low signal-to-noise ratios (S/N). Since its development, other methods have been reported that also utilize ALS algorithms, and they have a similar advantage with low S/N.$^{(8,9)}$ A second group of methods, which includes DTD, uses the generalized eigenvalue problem to decompose three-way data.$^{(5,10)}$ These methods are
non-iterative, and are especially effective when the data have a high S/N.

In some cases, the accuracy of the calibration may be threatened when unknown components in the sample interfere with the analyte response so that the analyte signal actually depends on the interferent concentration. In such situations, many of the methods mentioned above will be unable to predict the analyte concentrations reliably; this requires the use of a method for standard additions. Such a method exists that is analogous to the standard addition method commonly used with zero-order data: it is termed the second-order standard addition method (SOSAM), and has been shown to increase the reliability of the calibration when matrix effects exist in the sample.

Another tool that can improve calibration accuracy is data pretreatment. In some cases, where the raw data do not exactly fit the model upon which a particular method is based, a preprocessing technique may be of some assistance in improving the fit. For example, in cases where instrumental variations cause minute changes in analyte response from sample to sample, methods that rely on identical responses may fail. This is especially true in cases involving time series data, as the response in the time domain may not be exactly the same from run to run. One approach to solving this problem is to standardize the responses so that the instrumental variations are reduced. Second-order standardization methods are available that perform such an operation.

Other work that has been carried out in the second-order area and is related to calibration involves the figures of merit. These include net analyte signal, selectivity, sensitivity, limit of detection and S/N, and they can be used to aid in the development of better second-order instruments which will ultimately result in improved calibration due to improved data.

2 THREE-WAY MODELS

Calibration methods are based upon different models that describe the structure of the data. In calibration, the most commonly used model for second-order (three-way) data is the trilinear model. However, the trilinear model is actually one specific case of a broader model, the Tucker3 model. Tucker proposed his model for use in multiway psychology, in cases where the data contained three modes. His example was of individuals × traits × raters, and the aim of the analysis was to determine the underlying trends in each mode. The Tucker3 decomposition can be written as

Equation (4):

\[ r_{ijk} = \sum_{a=1}^{A} \sum_{b=1}^{B} \sum_{c=1}^{C} x_{ia} y_{jb} z_{kc} g_{abc} + e_{ijk} \]  

where \( r_{ijk} \) is a single data point in the three-way data block under analysis, \( x_{ia} \) is an element of the loading matrix from the first mode, \( y_{jb} \) is an element of the loading matrix from the second mode and \( z_{kc} \) is an element of the loading matrix from the third mode; \( g_{abc} \) is an element of Tucker’s core matrix, and represents the magnitude of any interactions between the modes, while \( e_{ijk} \) is an element of a matrix of residuals. This equation is written in matrix form as Equation (5):

\[ \mathbf{R} = \mathbf{XGY} \]  

Another form (Equation 6) was suggested by Geladi to eliminate confusion in the placement of the matrices:

\[ \mathbf{Y} \mathbf{R} = \mathbf{XGY} + \mathbf{E} \]  

The general decomposition described by these equations is visually represented in Figure 3. It can be seen that this decomposition allows a different number of factors to be present in each mode \( (a, b \text{ and } c) \), a fact that can complicate analysis. The core models interactions between factors by permitting nonzero elements on the off-diagonal. A unique solution is not obtained by this decomposition, however, as rotations can provide different solutions.

When the core is constrained to have nonzero elements only on the superdiagonal, a specific case of the Tucker3 model results. This model, the trilinear model, is much more restricted and can provide unique solutions. The calibration methods described later in this paper (e.g. DTD and PARAFAC) will generally use this trilinear model as in Equation (7):

\[ r_{ijk} = \sum_{n=1}^{N} x_{in} y_{jn} z_{kn} + e_{ijk} \]  

where \( N \) is the number of underlying factors in the data, \( x_{in} \) is an element of the loading matrix from the first

Figure 3 The Tucker3 decomposition; a core matrix, \( \mathbf{G} \), models the interactions between different factors.
Second-Order Calibration and Higher

5

mode, $y_m$ is an element of the loading matrix from the second mode and $z_{kn}$ is an element of the loading matrix from the third mode. This is also shown in matrix form in Equation (8a):\[ R = XYZ + E \] (8a)
or Equation (8b):\[ R = XIZ + E \] (8b)

The visual representation of this model is shown in Figure 4. Because the core matrix now just contains "ones" on the superdiagonal, and is, in effect an identity matrix, this is a trilinear model that does not allow interactions between modes. Another fact that simplifies analysis is that the number of factors in each mode must be the same: this requires a single rank estimation rather than three, which was the case with the Tucker3 model. In addition, the decomposition does not require the loading vectors $x$, $y$ and $z$ to be orthogonal, unlike the Tucker3 model, allowing the solutions to approximate more closely the true solutions found in analytical data which may not necessarily be orthogonal. The trilinear model is considered to be the most restricted model of all three-way models, and is the only one that allows a unique solution, provided the following condition is met: if $R$ is decomposed into factor matrices $X$, $Y$ and $Z$, and every $I$ column of $X$ is linearly independent, every $J$ column of $Y$ is linearly independent and every $K$ column of $Z$ is also independent, then $I + J + K \leq 2M + 2$, where $M$ is the number of columns in each of $A$, $B$ and $C$.

There are other special cases of the Tucker model, one of which is the basis of unfold principal component analysis (Unfold-PCA) and unfold partial least squares (Unfold-PLS) techniques. In this special case, the core matrix is not calculated, but is multiplied with two of the loading matrices. Only one of the loading matrices is explicitly calculated. This is performed by unfolding the data block along one of its ways, and placing each of the resulting "slices" side-by-side to form a new matrix. There are three possible ways to unfold the cube, but usually if two of the modes are linked or associated in some way, they are kept together. The possible models that underlie this procedure are specified in Equation (9a–c):

\[ r_{ijk} = \sum_{n=1}^{N} x_m h_{jkn} + e_{ijk} \] (9a)

\[ r_{ijk} = \sum_{n=1}^{N} y_m h_{ikn} + e_{ijk} \] (9b)

\[ r_{ijk} = \sum_{n=1}^{N} z_{kn} h_{ijn} + e_{ijk} \] (9c)

where $x_m$ is an element of the $(I \times N)$ score matrix $X$ and $h_{jkn}$ is an element of the loading matrix $H_n$.

The loading matrices $H_1$ to $H_n$ can be stacked and the three-way loadings matrix $H$ is obtained. Figure 5 shows one form of this unfolded model, corresponding to Equation (9a). This model does not produce a unique solution, as rotations will produce different solutions. In addition, there will more than likely be different residual matrices depending on which way the data block was unfolded.

3 Calibration Methods

There are many methods that have been published on solving three-way decompositions, which then allow quantitative analysis. Each model requires different techniques, and choosing the correct calibration method
therefore requires that the user know the type of data structure present. Booksh et al. discussed ways of choosing the calibration method, based on the theoretical instrument response function.\textsuperscript{(19)} If this is known, it may be compared with the models described below, and then the appropriate method may be used.

### 3.1 Alternating Least-squares Techniques

ALS methods have been used for second-order analysis for some years. PARAFAC is one such method that solves the trilinear model that is shown in Equation (4). This algorithm was first introduced in the psychometric literature in 1970.\textsuperscript{(7)} At the same time, an equivalent algorithm was introduced by a separate research group, who named their approach canonical decomposition (CANDECOMP).\textsuperscript{(20)} The approaches are equivalent, and use an ALS algorithm in their solution. The first application of this procedure in the chemical literature was by Appeloff and Davidson in 1980.\textsuperscript{(21)}

The first step in PARAFAC is to obtain initial estimates for two of its ways, for example, $X$ and $Y$ (Step 0 below). These guesses are then used to estimate the third way, $Z$. In the next step, $Z$ and $X$ are used to estimate $Y$, and then $Z$ and $Y$ are used to estimate $X$. The process continues in an iterative fashion until a specified ending criterion is met. The algorithm is given in Table 1.

#### 3.1.1 Step 0: Choosing the Starting Estimates

Choosing a starting estimate for two of the ways is the initialization step in the algorithm. A number of approaches are possible, but it must be noted that this choice will greatly affect how the algorithm proceeds, since the PARAFAC algorithm can become trapped in local minima so that convergence is slow and erroneous solutions can be produced.\textsuperscript{(22)} If there is a priori knowledge of the analyte profiles, these may be used. A random number generator is also a frequent choice.\textsuperscript{(23)}

In that case in particular, a wise decision is to consider many starting values, although this will considerably delay the process. If a number of different starting guesses give the same solution, then confidence in the accuracy of the result is greater. The closer the starting guesses are to the true solution, the faster the algorithm will proceed, and the probability of encountering local minima is reduced. Speed is a big consideration when using PARAFAC analyses, as convergence is usually very slow. Results obtained from DTD provide another option for starting estimates: when these results are not complex, this choice can speed up the convergence process.\textsuperscript{(24)}

#### 3.1.2 Step 1: Estimating the First Set of Profiles

In each of steps 1–3, the $R$ and $H$ matrices are working matrices, redefined at each step. $R$ is the data block, $R$, rearranged in matrix form, and $H$ is created from the parameters not being estimated in that step. When calculating the $Z$ profiles, therefore, the current $X$ and $Y$ information is employed to define $H$, as in Equation (10):

$$H^2H = (X^T X) \otimes (Y^T Y) \quad (10)$$

and Equation (11):

$$R^T H = \begin{bmatrix} \text{diag}(X^T R_1 Y)^T \\ \vdots \\ \text{diag}(X^T R_J Y)^T \end{bmatrix} \quad (11)$$

where $\otimes$ represents the Kronecker operator (element-wise multiplication), $R$ is the data block unfolded in the $K$ direction, so that $R_i$ is the $I \times J$ submatrix of $R$, and $\text{diag}(X^T R_i Y)^T$ is a column vector containing the diagonal of $X^T R_i Y$. At this step, Equation (12) is being minimized as

$$\min_z R^T - HZ^2 \quad (12)$$

#### 3.1.3 Steps 2 and 3: Estimating the Second and Third Sets of Profiles

The procedures for estimating $X$ and $Y$ are similar to that for determining $Z$, but in each case the $H$ and $R$ matrices are newly defined, using the parameters not being estimated.

#### 3.1.4 Step 4: Convergence

There are two main approaches that are used to determine when the solution has been reached and the iterations should be stopped. One of these is to compare changes in the fit after each iteration, stopping when the change in the residuals is less than a specified tolerance, generally close to $10^{-6}$. The residual change is calculated using the root of squared residuals. An alternative is to compare the loadings obtained after each iteration, stopping when they do not change more than a specified amount. This comparison is performed by calculating the angle between the predicted profile from successive iterations, which is

</table>
found in each case by unfolding the $X$, $Y$ and $Z$ matrices into column vectors and then calculating (Equation 13):
\[
\cos \theta_x \cos \theta_y \cos \theta_z = \frac{x_i x_{i+1}}{\sqrt{x_i^2 x_{i+1}^2}} \quad \frac{y_i y_{i+1}}{\sqrt{y_i^2 y_{i+1}^2}} \quad \frac{z_i z_{i+1}}{\sqrt{z_i^2 z_{i+1}^2}}
\]

where $x_i$ is from the $i$th iteration, and $x_{i+1}$ is from the following iteration. When this term is less than a specified criterion, for example $10^{-6}$ once again, convergence has been reached.

A difficulty that exists with PARAFAC is the occasional occurrence of two-factor degeneracies. This is signified when the estimated profiles for two components are highly correlated in all three modes. The uncorrelated correction coefficient (UCC) has been introduced to detect such a situation. The UCC for two components, $A$ and $B$, is (Equation 14):
\[
\text{UCC} = \frac{x_A x_B}{\sqrt{x_A^2 x_B^2}} \quad \frac{y_A y_B}{\sqrt{y_A^2 y_B^2}} \quad \frac{z_A z_B}{\sqrt{z_A^2 z_B^2}}
\]

where $x_A$, $x_B$ are the $x$ profiles, $y_A$, $y_B$ are the $y$ profiles and $z_A$, $z_B$ are the $z$ profiles of the two components. When the UCC is close to $-1$, a two-factor degeneracy has occurred. In that case, the profiles will be either positively correlated and two or more of the modes or negatively correlated in one or all three of the modes. Effectively, the results suggest that there is one factor fewer present than is actually the case. Sometimes it happens that a solution is close to degeneracy; this is indicated when the UCC is close to $-0.85$. This is not considered to be a true degeneracy, and further iterations may result in an improvement in the UCC as the solution moves closer to the real one. The temporary degeneracy can then be considered to be due to a local minimum, most likely due to a poor choice of initial estimates, and is known as a ‘swamp’. A true degeneracy may arise if the algorithm has been asked to calculate more factors than exist in the data. It may also occur if the wrong model has been chosen, i.e. if the trilinear model does not fit the data.

The existence of swamps is a source of difficulty, as extremely slow convergences may result. These are areas where the convergence slows dramatically, making it appear as though the solution has been reached. However, if the iterations are allowed to proceed, the slow convergence will once again become faster and the true solution will emerge. While the algorithm is in a swamp, the residuals will not change dramatically, whereas the loadings will. If a swamp is mistakenly thought to indicate convergence, therefore, the solution provided will not be accurate. Mitchell and Burdick have proposed that swamps tend to occur simultaneously with two-factor degeneracies, and caution must be exercised when these play a role in convergence. A solution that uses a stabilization method has been proposed, so that the number of iterations spent in a swap is greatly reduced. It is suggested that a high positive UCC may be indicative of serious problems due to instabilities in the estimation steps.

Constraints are generally imposed on the parameters to be estimated in order to increase interpretability. As was mentioned previously, PARAFAC was used in the psychometric field for some years before its applicability to chemical data was recognized. Psychometricians have employed a number of constraints, including orthogonal constraints, to overcome problems with unstable solutions to help convergence to the correct solution. (An orthogonal constraint helps with scaling; although scaling does not affect the uniqueness of the solution, it can be an issue in determining how long it takes to converge.) In chemistry, constraints are chosen based on a priori knowledge of the data being analyzed. For example, knowing that mass spectra, chromatographic profiles and concentrations are always positive, non-negativity constraints can be applied to all modes of a set of LC/MS samples. In addition, it is known that chromatographic profiles should be unimodal, allowing the imposition of a unimodality constraint. While non-negativity constrained least-squares techniques are common, however, the unimodality constraint is more difficult to impose.

The results that are obtained when PARAFAC is applied to excitation–emission data demonstrate the improvement that can occur when constraints are imposed. Samples that contained tyrosine, tryptophan and phenylalanine were measured by fluorescence, and unconstrained PARAFAC was used in an attempt to resolve the excitation and emission spectra. Figure 6(a) shows the emission spectra that were obtained. It is obvious that the profiles are not correct, as the spectra should be non-negative; however, when the concentrations and spectra are constrained to be positive, PARAFAC produces emission profiles (Figure 6b) that are very close to the true spectra (Figure 6c).

The only deviation from the true spectra is a slight hump below 300 nm, and this is reported to be due to non-multilinear Rayleigh scatter. Using the knowledge that the spectra should be positive enabled the analysts to use PARAFAC in such a way (i.e. with a non-negativity constraint) that the difficulties encountered could be overcome. These problems were most likely due to the small number of samples used, which in this case was just two. A related area of research in PARAFAC analysis is in increasing the algorithm’s efficiency by
Figure 6 Emission spectra from (a) unconstrained PARAFAC, (b) PARAFAC with non-negativity constraints and (c) true emission profiles. (Reprinted with permission from R. Bro, Chemom. Intell. Lab. Syst., 38, 149–171 (1997). Copyright 1997 Elsevier Science.)

Reducing the computations required,\textsuperscript{(26–29)} constrained algorithm's tend to reach convergence more quickly than the traditional versions, thereby resulting in research that combines the two.\textsuperscript{(30)}

PARAFAC has been applied to various analytical problems, and has resulted in the successful calibration of naphthalene and styrene in ocean water.\textsuperscript{(31)} In that case, an excitation–emission matrix imaging spectrophotometer was used, and the data contained a complex background signal in addition to overlapping spectral interferents that were not included in the calibration set. It was found that a two-factor PARAFAC model could be used to decompose the data so as to produce estimates of the excitation and emission profiles of naphthalene and background intensities in the samples. The factor that corresponded to naphthalene had a 2.6 ppb standard deviation of the blank, which equaled a limit of determination of 8 ppb, so that the measured linear dynamic range for naphthalene extended from 8 to 2000 ppb. When gasoline/naphthalene/ocean water samples were included in the decomposition, one extra factor was needed to account for the fluorescence spectrum of the gasoline; the question to be answered was whether or not the quantitation would be affected by the inclusion of these samples. Calibration curves were generated for both the two- and three-factor decompositions, where standard additions of naphthalene had been made to generate the standards. It was found that the quality of the calibration curve formed by the naphthalene/ocean water standards was not degraded by the presence of the gasoline as long as

An extra factor was included to account for its variation. Table 2 displays the prediction errors obtained in each calibration, and it is apparent that they are very similar, each having a root mean square error of prediction (RMSEP) of 47 ppb. However, three of the naphthalene standards deviate from linearity on the calibration curve; when these standards are excluded from the calibration, the RMSEP drops to <20 ppb in each case. The important conclusion that can be drawn from this analysis is that when second-order calibration techniques are employed, accurate analyte quantitation is possible even in the presence of large background signals and interfering chemical species.

An accurate calibration of a model system using flow-injection analysis/diode-array data has also been reported. Yet another investigation used PARAFAC to predict enzymatic activity and substrate consumption during the enzymatic browning of vegetables, while kinetic studies have also been investigated using this technique.

A recently published algorithm, the alternating trilinear decomposition (ATLD) algorithm, also solves the trilinear model with the aid of ALS, and is in fact an improvement of the traditional PARAFAC algorithm without constraints. While it does not involve the use of constraints, it still converges faster than the original PARAFAC algorithm (ATLD is reported as converging in less than ten iterations), and its iterative procedure uses the Moore–Penrose generalized inverse with singular value decomposition (SVD) in the trilinear sense. As mentioned previously, some of the main drawbacks to the use of PARAFAC are (a) the occurrence of two-factor degeneracies and (b) the presence of swamps. ATLD was developed with the aim of regularizing the procedure, thus avoiding these traps. The loss function to be minimized in this case is (Equation 15):

$$\sigma = \sum_{i=1}^{I} \sum_{j=1}^{J} \sum_{k=1}^{K} (r_{ijk} - \sum_{n=1}^{N} x_{in} y_{jn} z_{kn})^2$$

where the symbols have the same meanings as before. In order to solve the loss function, the algorithm alternates over Y for fixed X and Z, over X for fixed Y and Z, and over Z for fixed X and Y. The equations that are solved at each step are (Equations 16a–c):

$$x_i^T = \text{diag} (Y^T R_i (Z^T)^+), \quad i = 1, \ldots, I \quad (16a)$$
$$y_j^T = \text{diag} (Z^T R_j (X^T)^+), \quad j = 1, \ldots, J \quad (16b)$$
$$z_k^T = \text{diag} (X^T R_k (Y^T)^+), \quad k = 1, \ldots, K \quad (16c)$$

where $R_i$, is the data cube $R$ unfolded along the $J \times K$ axis. These equations involve the use of the Moore–Penrose generalized inverse, denoted by the superscript, whereas the original PARAFAC algorithm did not (see Equation 11). Because this computation is based on the SVD, singular values less than a certain tolerance are treated as zero. This makes it possible to perform the calculations even when $N$ is greater than the number of chemical species present in the sample, reducing the rank deficiency problem that exists with PARAFAC and that can cause two-factor degeneracies. The importance of this result stems from the fact that rank determination is not always straightforward, especially in the presence of noise, and an overestimation of the number of chemical species in the sample may sometimes occur.

A comparison of the ATLD and traditional PARAFAC algorithm has been carried out on liquid chromatography/diode-array detection (LC/DAD) data for overlapped chlorinated aromatic hydrocarbons. The analytes were p-chlorotoluene and o-chlorotoluene, with o-dichlorobenzene being an interfering species (i.e. not included in the calibration set). Four samples were included in the calibration set, while there were three test samples. Table 3 shows the true concentrations of the analytes in each sample, along with the predicted concentrations that were given by both the traditional PARAFAC algorithm and the ATLD algorithm.

The concentration estimates are, in general, closer to the true values than the PARAFAC predictions; moreover, convergence was reached much more quickly with the ATLD algorithm. It must also be noted that the standard deviations of the ATLD predictions are much smaller than those of the PARAFAC predictions. However, it is known that PARAFAC performance can
be improved through the use of constraints, and such an algorithm may have performed better.

Another method that uses an ALS algorithm is MCR. As the name suggests, this technique was originally developed for resolution of the profiles in second-order data.\(^\text{(9,35,36)}\) However, further development of the method has allowed the calibration of three-way data in addition to profile resolution.\(^\text{(37)}\)

There are three main steps that are carried out during this procedure. First, the chemical rank of the data, \(N\), must be determined. Generally, SVD may be used. By examining the singular values in regions where no chemical components exist, variance due to noise can be estimated. Once the noise estimate is known, singular values due to the chemical components can be determined in different regions of the data, thereby allowing pseudo-rank estimation.

As with other techniques that employ ALS, initial estimates of the profiles are required. In this case, however, only a concentration profile estimate is needed. Evolving factor analysis (EFA) is used,\(^\text{(38)}\) and for a specific reason: it is known that, in order to use curve-resolution methods, assumptions must be made about the signal. Common assumptions include bilinearity, non-negativity, unimodality and closure. However, even with such constraints, a unique solution (for the analysis of a single sample) is not guaranteed, as rotational and intensity ambiguities may still exist.\(^\text{(9)}\) The use of EFA allows curve resolution to overcome, in part, the rotational ambiguity, as it provides information regarding the windows of existence of components in the data. Of course, when multiple samples are analyzed simultaneously, the rotational ambiguity no longer exists, but EFA remains a good choice for initial estimates. The third step to be taken when performing MCR is to calculate iteratively new profiles using constrained ALS. When a single sample is being analyzed (Equation 17):

\[
\mathbf{D} = \mathbf{C}\mathbf{S}
\]

where \(\mathbf{D}\) is a bilinear data matrix, dimensioned \(m \times n\), \(\mathbf{C}\) is a matrix of concentration profiles, dimensioned \(m \times N\), and \(\mathbf{S}\) is a matrix of spectral profiles, dimensioned \(N \times n\). It can be seen that this is not the trilinear model used by PARAFAC and the eigenvalue–eigenvector-based methods, as the concentration information is contained within the concentration profiles rather than being separately calculated.

The initial estimates of the concentration profiles in \(\mathbf{C}\), obtained by EFA, are then used to calculate the corresponding spectra (Equation 18):

\[
\hat{\mathbf{S}} = \mathbf{C}^*\mathbf{D}
\]

where \(\mathbf{D}\) has been truncated to rank using SVD. The following step involves a new estimation of \(\mathbf{C}\), using the new spectral profiles, \(\hat{\mathbf{S}}\) (Equation 19):

\[
\hat{\mathbf{C}} = \mathbf{D}\hat{\mathbf{S}}^\dagger
\]

The algorithm iterates back and forth between Equations (18) and (19) until the stopping criterion is met. This criterion is similar to PARAFAC ending criteria.

There are a number of constraints that may be used, based on the previously mentioned assumptions. Constraining the spectra and concentration profiles to have non-negative values is common, while the shape of the signal may also be a constraint. For example, a unimodality constraint is frequently imposed upon chromatographic profiles. As mentioned already, however, the use of such constraints will not always remove the ambiguity problems. Analyzing two or more samples simultaneously, on the other hand, often allows a unique solution. In addition, quantitation in the presence of unknown analytes becomes possible: the second-order advantage.\(^\text{(39,40)}\)

In order to use MCR for calibration, the data matrices to be analyzed must be arranged in one matrix. They may be concatenated in three ways: row-wise, column-wise or along the tubes. Samples are concatenated so that the columns, or spectra, are in common (Equation 20a):

\[
\mathbf{D}_s = \mathbf{C}_s\mathbf{S}
\]

or (Equation 20b)

\[
\mathbf{D}_1 = \mathbf{C}_1
\]

\[
\mathbf{D}_2 = \mathbf{C}_2
\]

\[
\vdots = \vdots
\]

\[
\mathbf{D}_s = \mathbf{C}_s
\]

\(\mathbf{D}_s\) is dimensioned \(m's \times n\), \(\mathbf{C}_s\) is \(m's \times N\) and \(\mathbf{S}\) is \(N \times s\), where \(s\) is the number of samples, \(N\) is the number of principal components required to describe the data and \(m \times n\) are the dimensions of each individual \(\mathbf{D}\) matrix. It can be seen that \(\mathbf{S}\), which contains the spectral profiles, is common to each individual sample, while the concentration profiles vary.

The quantitative results are obtained through the resolved concentration profiles in \(\mathbf{C}\). Since the concentration information is embedded in the profiles, the area under the curves can be related to concentration. When calibration standards are included in the MCR analysis, the unknown analyte concentrations can be found via Equation (21):

\[
c_{\text{un}} = \frac{A_{\text{un}}}{A_{\text{std}}}c_{\text{std}}
\]

where \(c_{\text{un}}\) and \(c_{\text{std}}\) are the unknown and standard concentrations for a particular analyte, and \(A_{\text{un}}, A_{\text{std}}\)
are the areas under the resolved profiles for that analyte in the unknown and standard samples.

With MCR analysis, it is possible to analyze data matrices that do not strictly follow a trilinear data structure when concatenated. Although each individual matrix must be bilinear, the profiles of one mode may vary. For example, if the data are chromatographic/spectrometric, the chromatographic profiles may vary in retention time and/or shape from one sample to the next. Such data do not have a trilinear data structure, and methods that rely on a trilinear model will fail. By constraining the spectra to be equal, but not the concentration profiles, MCR can resolve the profiles and also obtain adequate quantitative results.\(^{(37)}\)

For example, quantitative analysis using second-order MCR has been applied to mixtures of amino acids that were measured with flow-injection analysis and diode-array multiwavelength detection.\(^{(39)}\) The system monitored the reaction of lysine and proline with 1,2-naphthoquinone-4-sulfonate (NQS). Four samples were analyzed, water, lysine, proline and a mixture of lysine and proline, all of which were injected into a system containing NQS. This data is not trilinear; whereas the concentration profiles of the amino acid derivatives retain their shapes over the course of the reaction, the shapes of unreacted NQS species vary depending on the amino acid concentration in the mixture. The three-dimensional data from the mixture of lysine and proline are shown in Figure 7.

The sample data matrices were concatenated and analyzed as described above, and Table 4 shows the predicted concentrations that were obtained under a number of different constraints (options a–d). The fitting error of the resolved profiles is also reported.

Because of the nontrilinear nature of the data, option c (which forces both concentration and spectral profiles to be identical and therefore assumes trilinearity) does not give the best quantitative results, producing a quantitation error of 3.34%. Conversely, option d constrains only the concentration profiles of the amino acid derivatives to be the same, and this more flexible option produces much better quantitative results with a quantitation error of 0.36%.

In contrast, when data with a trilinear structure are analyzed, the concentration profiles can be constrained to be identical in addition to the spectral profiles. In that case, the additional constraint improves both quantitative and qualitative results. It has been found that when data follow the trilinear data structure, the predictive error is much lower.

\(^{a}\) Applied constraints: (a) no closure or equal shape constraint; (b) closure constraint with respect to NQS; (c) closure constraint with respect to NQS and equal shape constraint to all concentration profiles; (d) closure constraint with respect to NQS and equal shape constraint to only the derivative concentration profiles.

\(^{b}\) Fitting error (%) = \(\frac{(A_{ij,\text{experimental}} - A_{ij,\text{reproduced}})^2}{A_{ij,\text{experimental}}}^{1/2} \times 100\), where \(A_{ij,\text{experimental}}\) is the experimental absorbance at wavelength \(j\) and time \(i\) and \(A_{ij,\text{reproduced}}\) is the reproduced absorbance obtained by MCR.

\(^{c}\) Quantitation error (%) = \(\frac{(C_{\text{known}} - C_{\text{calc}})^2}{C_{\text{known}}}^{1/2} \times 100\), where \(C_{\text{known}}\) is the known concentration of each analyte, Lys and Pro, in the unknown sample and \(C_{\text{calc}}\) is the calculated concentration of each analyte recovered from MCR.

---

within the level of measurement noise.\(^{41}\) In cases where only one order is identical from one sample to another, the error is higher, but still within acceptable limits, provided that there is some selectivity present for the analyte in question. If complete overlap exists, then the results will be ambiguous.\(^{40}\) Comparison studies have been carried out between MCR and DTD, an eigenproblem-based method that operates specifically on trilinear data, and the results indicate that each method’s performance is comparable for trilinear data.\(^{41}\) It has also been suggested that a simple method for determining the presence or absence of trilinearity might be to compare the lack of fit obtained with DTD and MCR. This is because data that fit the trilinear model will be fitted well with DTD, whereas deviations from trilinearity will result in a better fit with MCR.\(^{42}\)

### 3.2 Rank Annihilation Methods

Calibration methods that use rank annihilation have been used in the chemical field for almost 20 years, and they have undergone many changes and improvements in that time. The first form of rank annihilation factor analysis (RAFA) was introduced by Ho et al. in 1980.\(^{43–45}\) That method suffered from being very slow, as it employed iterative methods for its solution. When an improved version of RAFA was proposed by Lorber 4 years later, the problem was transformed into an eigenvalue problem that could be directly solved in a very short time.\(^{46}\) In this method, two samples were required for calibration. One was the unknown or test matrix that was to be analyzed, \(M\), while the second was the calibration sample, \(N\), that could contain just one of the analytes present in \(M\). Both \(M\) and \(N\) must follow the bilinear data format, where the mixture matrix, \(M\), can be represented by Equation (2), and the pure standard matrix, \(N\), can be represented by Equation (1). The \(k\)th component in \(M\) is common to both samples.

These equations can be rearranged to form a generalized eigenvalue problem (Equation 22):

\[
N_k z_k = \lambda_k M z_k
\]  
(22)

where \(\lambda_k\) is an eigenvalue that is equivalent to the concentration of the \(k\)th analyte in \(N\) divided by its concentration in \(M\). \(z_k\) is an eigenvector that was later shown by Sanchez and Kowalski to be related to the response profile of the analyte.\(^{43}\) However, because \(M\) and \(N\) are not necessarily square, the problem as written may not be solved. \(M\) is therefore truncated using SVD (Equation 23):

\[
M = USV^T
\]  
(23)

Equation (22) is rewritten as Equation (24):

\[
x_k y_k^T z_k = \lambda_k USV^T z_k
\]  
(24)

and an eigenvalue problem is formed (Equation 25):

\[
U^T x_k y_k^T VS^{-1} z' = \lambda_k z'
\]  
(25)

where \(U\), \(S\) and \(V\) are the SVD factors truncated to the number of principal components in \(M\), \(x' = SV^T z_k\), \(U^T x_k y_k^T VS^{-1}\) is square, and \(z'\) is the eigenvector to be found. The column and row profiles, \(y_k\) and \(x_k\), may be found (Equation 26):

\[
y_k = (VS^{-1} z')^T; \quad x_k = Nz_k c_{n,k}
\]  
(26)

This formulation of RAFA (minus the use of Equation 26), when introduced, decreased computation time, and it also overcame a problem that had existed with the original version. In using that particular method, it was necessary to decide which eigenvalues should be examined to find the minimum which indicates rank annihilation; the use of an eigenvalue problem eliminates that need.

The form of RAFA that is generally applied today is called generalized RAFA, also known as GRAM.\(^{4,47}\) This technique allows the simultaneous quantitation of multiple analytes, whereas the earlier RAFA formulations permit the quantitation of just one analyte at a time. Again, one standard matrix, \(N\), is required for the calibration of one sample matrix, \(M\). However, in this case, the standard and the test samples may contain unknown interferents that will not affect the calibration; this is the second-order advantage previously mentioned.

The first step that must be taken in a GRAM analysis is to find joint basis sets for the analyte signals in \(M\) and \(N\). The fact that interferents may be present in either \(M\) or \(N\) means that projection of one matrix on to the principal components of the other (as in Lorber’s method, Equation 25) will change the information present and result in an inaccurate calibration. GRAM overcomes this by finding the principal components from both matrices. There have been a few suggestions on the best way to calculate the principal components: Sanchez and Kowalski proposed calculating them from the sum of \(M\) and \(N\)\(^{4}\) thereby producing (Equation 27):

\[
W = M + N = UW SW V'_W^T
\]  
(27)

where \(U_W\) and \(V'_W\) are the principal components of the joint row and column spaces. Wilson et al. found the principal components as\(^{47}\) (Equation 28):

\[
M/N = QSV^T
\]  
(28a)

\[
M/N = PSV^T
\]  
(28b)

\(M/N\) is obtained by concatenating the matrices row-wise, whereas \(M/N\) is obtained through the column-wise
concatenation of $M$ and $N$. $Q$ and $P$ are the joint row and column spaces found by this technique.

Following the principal component calculation, the eigenvalue problem must be formulated. There are a number of ways to calculate the eigenvalues and eigenvectors from which the concentration ratios and row and column profiles are determined. Either a standard eigenproblem or a generalized eigenproblem may be solved. The standard eigenproblem is similar to Lorber’s formulation for a single component, as it involves projecting the test sample matrix onto the principal components of the calibration matrix, and is shown using the singular vectors from Equation (27) (Equation 29):

$$ (U_W^T M V_W S_W^{-1}) Z_W = Z_W \Lambda $$

(29)

where $U$, $S$ and $V$ calculated in Equation (27) have been truncated to the number of principal components present in $W$ and $Z_W = S_W W_V Z$ and $Z$ is a matrix of eigenvectors. In this case, $\Lambda$ is a diagonal matrix that consists of the concentration ratios for all of the components common to $M$ and $N$. It should be noted that the ratios that result from this formulation are (Equation 30):

$$ \lambda_k = \frac{c_{n.k}}{c_{n,k} + c_{m,k}} $$

(30)

where $c_{n,k}$ and $c_{m,k}$ are the concentrations of analyte $k$ in $N$ and $M$, respectively. This means that if a component is not present in the calibration sample ($N$), $\lambda_k = 0$, while $\lambda_k = 1$ if a component is not present in the unknown sample ($M$). From this, the analyst can determine which components are present in either or both samples. The row and column profiles of each analyte common to both matrices may also be found (Equation 31):

$$ Y^T = (V_W S_W^{-1} Z_W)^T; \quad X = U_W W_C C_m^{-1} $$

(31)

An alternative formulation of GRAM uses the generalized eigenvalue problem. It has a similar form to Equation (22), but in this case there are multiple analytes in both calibration matrices (Equation 32):

$$ MZ = NZ \Lambda $$

(32)

where $Z$ is a matrix of eigenvectors and $\Lambda$ is a diagonal matrix of eigenvalues. If $M$ and $N$ are square, this equation can be solved directly using the QZ algorithm. However, $M$ and $N$ are generally rectangular matrices, and therefore a projection operation is needed to make them square. The principal components for the joint row and column spaces from either Equation (27) or (28) may be used, and this then leads to Equations (33a) and (33b):

$$ M_{PQ} = F^T M_Q $$

(33a)

$$ N_{PQ} = F^T N_Q $$

(33b)

where $M_{PQ}$ and $N_{PQ}$ are square and $P$ and $Q$ are truncated principal components from Equation (28). The eigenproblem can then be rewritten as Equation (34):

$$ M_{PQ} Z_Q = N_{PQ} Z_Q \Lambda $$

(34)

where $Z_Q = (Y_Q)^T$. $\Lambda$ is a diagonal matrix that contains eigenvalues of the form $c_{k,m}/c_{k,n}$. Use of the QZ algorithm has the advantage that it yields two matrices $\alpha$ and $\beta$ where $\Lambda = \alpha/\beta$, rather than calculating $\Lambda$ directly. This means that there is no danger of running into difficulties when the calibration matrix, $N$, is missing an analyte that is present in $M$. With the original method (Equation 29), this scenario would have led to a calculation of 1 divided by 0. The analyte concentrations in the test matrix, $M$, may be calculated from this relation if the concentrations in $N$ are known, and vice versa. As with the previous description of GRAM above, the row and column profiles can then be found (Equation 35):

$$ Y = Q(Z^*)^T; \quad X = P(N_{PQ} + M_{PQ}) Z $$

(35)

The use of the generalized eigenvalue problem and QZ algorithm is preferable in situations where construction of the factor space has not been performed with maximum precision.

There is another modification to the GRAM algorithm that in some instances can prevent the occurrence of complex solutions. It applies to the GRAM formulation that uses the QZ algorithm, and simply involves projecting the sum of $M$ and $N$ (i.e. $W$) rather than $M$ alone when formulating the eigenproblem. This makes the QZ formulation more similar to the original Sanchez–Kowalski method. In the case of the generalized eigenvalue problem, Equation (33a) becomes Equation (36):

$$ W_{PQ} = F^T WQ $$

(36)

and Equation (34) is rewritten as Equation (37):

$$ W_{PQ} Z_Q = N_{PQ} Z_Q \Lambda $$

(37)

such that $\Lambda$ now contains eigenvalues as per Equation (30) rather than the $c_{k,m}/c_{k,n}$ ratios that are obtained from the eigenproblem in Equation (34). The advantage of this variant is that it is numerically more stable, because the eigenvectors that are calculated are common to both of the matrices under analysis, $W$ and $N$. In cases where the analyte profiles of the common components in $M$ and $N$ vary, such as in situations where retention time shifts are present, the use of this version avoids the complex solutions that can result from dissimilarities in the matrices analyzed.

The utility of GRAM is demonstrated in an application that quantitates ethylbenzene and $m$-xylene, in a white gas mixture that was analyzed by GC x GC.

a Quantifying resolved peaks by peak area using a reference single-column gas chromatography (GC) method.
b Quantifying incompletely resolved components in GC × GC by GRAM.
c RSD is the relative standard deviation of predictions, expressed as a percentage.
d Set 6 used as standard. Compound concentrations were determined gravimetrically during sample preparation.

It can be seen that, for most of the samples, the GRAM results compare favorably with those of the reference method (where the gasoline samples were run on a conventional one-dimensional gas chromatograph so that all components were fully resolved). For the samples with low concentrations, however, the prediction error is fairly high. For ethylbenzene in sample 1, for example, the prediction is 22% lower than that of the reference method. The reason for this may be due to the large difference in ethylbenzene concentration between the sample and standard, as the level of ethylbenzene in the standard was 35 times greater than that in the sample, implying that analyte concentrations in the sample and standard should be similar in order to obtain accurate and precise quantitation with GRAM.

As was mentioned previously, complex results from GRAM are occasionally obtained. In fact, the eigenvalues and eigenvectors from the generalized eigenvalue
problem are guaranteed to be real only when \( \mathbf{M} \) and \( \mathbf{N} \) are positive definite and nonsingular. As they are generally real, unsymmetrical rectangular matrices, complex solutions will result at times. In particular, when the shape and retention time of any analyte vary between \( \mathbf{M} \) and \( \mathbf{N} \), perhaps owing to the presence of a high-noise signal, or at other times to variations in instrumental conditions, complex results are produced. In such cases, the imaginary part of the estimated row and column profiles is too large to be attributed to round-off error. However, when such a problem arises, there is a solution in the form of a similarity transform.\(^{(5)}\)

The success of the similarity transform is due to the fact that it can rotate the imaginary part of the complex solution to the real plane, and this can be achieved when complex eigenvalues and their corresponding eigenvectors occur in conjugate pairs. However, because eigenvalues and eigenvectors from the QZ algorithm do not always occur in this fashion, a preliminary step is required before the transform is applied. This first step following the solution of the eigenproblem is to order the eigenvalues and eigenvectors in descending order: the complex conjugate pairs of eigenvalues are grouped together by this operation. A preliminary transform, \( \mathbf{T}_1 \), is then carried out to group real eigenvalues with their corresponding eigenvectors. The direction of a complex number in the complex plane can be changed by multiplication with \( e^{i\theta} \) without changing its magnitude. When eigenvalues occur in complex conjugate pairs but eigenvectors do not, it is therefore possible to find two arguments \( \alpha \) and \( \beta \) that transform the eigenvectors simultaneously to complex conjugate pairs. The elements of \( \mathbf{T}_1 \) that perform this operation are \( e^{i\alpha} \) and \( e^{i\beta} \). The operation on the eigenvalues and eigenvectors is

\[
\mathbf{Z}' = \mathbf{Z}(\mathbf{T}_1)^{-1} \quad \text{(38a)}
\]
\[
\Lambda' = \mathbf{T}_1 \Lambda (\mathbf{T}_1)^{-1} \quad \text{(38b)}
\]

Finally, a second transform (the similarity transform, $T_2$) is found which transforms the complex eigenvalues and eigenvectors to real eigenvalues and eigenvectors. The elements of $T_2$ for a complex conjugate pair are (Equation 39):

$$
\begin{bmatrix}
  t_{2,ij} & t_{2,j+1} \\
  t_{2,i+1,j} & t_{2,i+1,j+1}
\end{bmatrix} = \begin{bmatrix}
  1 & 1 \\
  1 & -1
\end{bmatrix}
$$

(Equation 39)

The $T_2$ matrix is applied to the eigenvalues and eigenvectors that are produced by the first operation displayed in Equation (38), to give Equations (40a) and (40b):

$$
Z^{*} = Z^*(T_2)^{-1} \quad (40a)
$$

$$
\Lambda^{*} = T_2\Lambda^*(T_2)^{-1} \quad (40b)
$$

The effectiveness of this transform has been shown in the determination of unbound hydrocortisone in urine. LC/DAD was used to measure a real urine sample in addition to a standard hydrocortisone sample. When these data were analyzed by GRAM, complex values appeared in both the eigenvectors, $V$, and the eigenvalues, $A$ (see Table 6) thereby requiring the use of the transform.

Following this procedure, the imaginary parts of the eigenvalues and eigenvectors had disappeared, as can be seen in Table 7.

The validity of the results is evident upon examination of the true hydrocortisone concentration ratio (33.3%) versus that produced by the modified GRAM algorithm (34.6%). The source of the imaginary numbers in this case is always present in such a case). GRAM is very sensitive to retention time shifts, as stated above, thereby producing a bias in the estimated concentration ratios. A theoretical study of bias and variance in the estimated eigenvalues and eigenvectors to real eigenvalues and eigenvectors.

Equation (38), to give Equations (40a) and (40b):

$$
\begin{align*}
Z^{*} &= Z^*(T_2)^{-1} \\
\Lambda^{*} &= T_2\Lambda^*(T_2)^{-1}
\end{align*}
$$

(Equations 40a and 40b)

The agreement of the study with heteroscedastic noise to the simulations thereby lends credence to the theory that the presence of homoscedastic noise is an unrealistic assumption, and does not adequately describe real systems.

GRAM can be extended to allow a TLD, also known as DTD. GRAM is actually the simplest case of a third-order tensor, with only two slices in the third-order. When more than two slices are present, DTD can be applied to project all slices to just two, followed by SVD which finds a joint row, column and sample space.

The input to the algorithm is an $I \times J \times K$ block of data. The data are unfolded along each order, and in each case the resulting matrices are decomposed by SVD, as mentioned above. The left singular vectors for the first $n$ principal components are retained from the decomposition of the joint row and column spaces, but in the case of the joint sample space, only the first two singular vectors are retained, to give Equations (41a–c):

$$
\begin{align*}
[R_1 | R_2 | R_3 | \cdots | R_K] &= U_S V_T^T \\
U &= U_r(I \times N) \\
V &= U_c(J \times N) \\
W &= U_w(K \times 2)
\end{align*}
$$

(Two representative matrices are then generated using Equations (42a) and (42b):

$$
G_1 = \sum_{k=1}^{K} w_k U_T R_k V \\
G_2 = \sum_{k=1}^{K} w_k U_T R_k V
$$

The first two columns of $W$ are suitable for calculating representative matrices because they are the “scores” of the first two principal components, and are therefore likely to contain contributions from all components. GRAM is then carried out on $G_1$ and $G_2$ to find $X$, $Y$ and $Z$, where $Z$ is generally the concentration order. The generalized

Effects of model errors in GRAM have also been investigated. Matrix effects can be minimized through the use of standard addition, while interaction effects cannot (because a cross-term between concentrations is present in such a case). GRAM is very sensitive to retention time shifts, as stated above, thereby producing a bias in the estimated concentration ratios. A theoretical study of bias and variance in the estimated eigenvalues and eigenvectors to real eigenvalues and eigenvectors.

a From Li et al.53)
b Using the algorithm from Sanchez and Kowalski.55)
eigenproblem that is solved is (10) (Equation 43):

\[ G_1 \Psi = G_2 \Psi \Lambda \]  

(43)

\[ \mathbf{X} \text{ and } \mathbf{Y} \text{ are then determined from the calculated eigenvectors (Equation 44):} \]

\[ \hat{\mathbf{Y}} = \mathbf{V} (\Psi \Psi^T)^{-1} \]  

(44)

\[ \hat{\mathbf{X}} = \mathbf{U} G_2 \Psi \]  

where (Equation 45):

\[ R_k = \sum_{n=1}^{N} z_n x_n y_n^T + E_k \]  

(45)

The full \( \hat{\mathbf{Z}} \) (\( \mathbf{K} \times \mathbf{N} \)) matrix can be calculated simultaneously by Equation (46):

\[ \hat{\mathbf{Z}} = \mathbf{P} \mathbf{Q}^{-1} \]  

(46)

and (Equation 47):

\[ p_{kn} = \sum_{i=1}^{I} \sum_{j=1}^{J} r_{ijk} \hat{x}_{in} \hat{y}_{jn} \]  

(47)

and (Equation 48):

\[ \mathbf{Q} = (\hat{\mathbf{X}} \hat{\mathbf{X}}^T) \cdot (\hat{\mathbf{X}} \hat{\mathbf{X}}^T) \]  

(48)

Therefore, Equation (52):

\[ \mathbf{R}_1 + \mathbf{R}_2 \neq \hat{x}_a \hat{y}_a \]  

(52)

On the other hand, when Equations (43) and (44) are used, it is found that the quantitation results are identical with GRAM, and the prediction error is only 0.09%.

Similarly to GRAM, DTD occasionally has problems with complex solutions. This has been addressed with the use of similarity transforms, as with GRAM.57) In this case, the transform is carried out on \( \Psi \) and \( \Delta \) from the eigenvalue problem. However, the similarity transform, when applied to DTD decomposition factors, contains a rotational ambiguity. This means that when eigenvectors have occurred in complex pairs, the resulting chromatograms and spectra are not uniquely identified. The use of similarity transforms to eliminate the problem of complex solutions is therefore not as widely applicable to DTD data as to GRAM.

The rank annihilation methods have been applied in many different situations. GRAM has been successfully applied to LC/UV data, and also to bimodal chromatography data.58,59) A unique application involved
nuclear magnetic resonance (NMR) data, where a single multicomponent pulsed-gradient spin-echo nuclear magnetic resonance (PGSE-NMR) data set was analyzed by GRAM.\(^{60}\) This was possible because PGSE-NMR data consist of exponential decaying profiles, and the authors were able to “create” two data sets from a single one by using spectra 1 to \(n - 1\) for the first set and spectra 2 to \(n\) for the second set. Despite the highly overlapped nature of the data, GRAM could resolve the spectra of the two components present. Another extension or application of DTD is direct trilinear decomposition with matrix reconstruction (DTDMR).\(^{61}\) This method is suitable for cases where one of the responses is actually a matrix. GRAM and DTD have both been used to predict heavy metal concentrations, from data obtained from a second-order fiber-optic heavy metal sensor.\(^{62}\) The signals in each order were time and wavelength, respectively, and unknown interferents were present. The GRAM and DTD predictions both gave improvements over a zero-order analysis, which gave a positive bias. It was found, however, that when the sensor response deviated from linearity, the prediction errors increased, as is to be expected from these methods when the trilinear model is not held. In a separate study, DTD was used to resolve mathematically porphyrins from emission–excitation fluorescent spectra of canine and feline dental calculus deposits.\(^{63}\) The small quantity of samples in that study had made physical separation and analysis unfeasible.

Although the trilinear model is the most commonly employed model for second-order calibration, there are cases where data do not fit this model. For example, when an instrument response is such that a pure analyte has a rank of >1, the data are nonbilinear. In such a case, application of any of the methods that specifically solve that type of data will not be of benefit, and may in fact result in an unreliable calibration. NBRA is a method that enables calibration of nonbilinear data when the response matrix of the pure analyte is available as a calibration standard.\(^{6,64}\) The method is based on the model in Equation (53):

\[
N = \sum_{p=1}^{P} x_p c_p y_p^T
\]  

where \(N\) is a data matrix of a single pure component from a second-order instrument that produces nonbilinear data, \(P\) is the total number of detected components in the mixture, \(x\) and \(y\) are factors relating to the response profiles and \(c\) is related to concentration. The factors can be approximated using any three-way decomposition method, such as an eigenvalue–eigenvector decomposition, but it must be noted that the bilinear components from the decomposition do not contain the chemical and physical meaning that they do for bilinear data. (Approximating nonbilinear data using an eigenvalue–eigenvector decomposition is analogous to using PLS or PCR to approximate nonlinear first-order data with extra factors.)

It can be seen, therefore, that the greatest difference between nonbilinear and bilinear data lies in \(P\), the number of factors in the data. For a pure component in a bilinear response matrix, there is one detectable factor present, as previously explained and shown in Equation (1). In other words, the rank of the matrix in the absence of noise is 1. On the other hand, the rank in a nonbilinear response matrix for a pure component is >1, so that when a second-order decomposition is carried out more than one concentration estimate is obtained.

A figure of merit that may be calculated to determine the reliability of the calibration on a particular data set is the rank linear additivity (RLA). It can be said that RLA holds if the rank of a mixture, \(M\), is equal to the sum of the ranks of individual components in the mixture. In that case, different components do not overlap with respect to their rank. For example, if \(M\) consists two components, \(a\) and \(b\), whose instrument responses can be represented as in Equation (54a):

\[
M_a = c_a (x_1 y_1^T + x_2 y_2^T)
\]  

and Equation (54b):

\[
M_b = c_b (x_3 y_3^T + x_4 y_4^T)
\]  

where \(c_a\) and \(c_b\) are the concentrations of the components, and (Equation 55):

\[
M = M_a + M_b
\]  

then the calibration is similar to the case of bilinear components with identical concentrations. In such a case, the response profiles are not resolved because they are linearly combined, but the concentration prediction is accurate.\(^{10}\) In this case, \((x_1, x_2)\) and \((y_1, y_2)\) would be linear combinations of one another, as would \((x_3, x_4)\) and \((y_3, y_4)\), but the four concentration estimates will simply be \(c_a\) repeated twice, and similarly for \(c_b\).

If RLA does not hold, then the calibration becomes more complicated, because the components are now overlapping in rank. For example, if (Equation 56):

\[
M = c_1 x_1 y_1^T + c_2 x_2 y_2^T + c_3 x_3 y_3^T + c_4 x_4 y_4^T
\]  

then the rank of \(M\) equals 3 rather than 4.

Here it can be seen that \(x_2 = x_4\), so that these factors, from different components, are not independent. What will happen when a decomposition is carried out? Will it be possible to calculate the concentrations of these
analytes? In a case such as this, it is important to calculate the net analyte rank (NAR).

NAR may be defined as (Equation 57):

$$\text{NAR}(\mathbf{N}) = \text{rank}(\mathbf{M}) - \text{rank}(\mathbf{M|N})$$  \hspace{1cm} (57)

where \(\text{rank}(\mathbf{M|N})\) is the rank of mixture \(\mathbf{M}\) in the absence of the pure analyte \(\mathbf{N}\). If the NAR is equal to at least one, then calibration is still possible: it has been determined that NBRA retains the second-order advantage as long as the “NAR” of the data is \(\geq 1\).\(^{165}\) In this case, shown in Equation (54), if the NAR is calculated for component \(a\), then NAR \(= 3 - 2 = 1\). When the decomposition is carried out, therefore, the concentration estimate corresponding to the \(x_iy_j\) factor will be \(c_{ij}\). The same situation holds for analyte \(b\) in this case. There is another way to determine the correct concentration estimate when there is just one analyte in the calibration sample, \(\mathbf{N}\). This procedure requires NBRA to be repeated using different multiples of \(N\) in place of \(N (\epsilon \times N)\), and the resulting concentrations which are proportional to \(1/\epsilon\) are chosen as the correct concentration estimates. The corresponding \(x_i, y_j\) pairs then comprise the net analyte signal.

Whether or not the data can be calibrated depends considerably on the instrument on which the data is collected. If the instrument produces data whose nonlinearities are polynomial in nature, then the data in general can be described by a low rank, and the NAR will generally be \(\geq 1\). If the nonlinearities are more complex, the rank will be higher and the bilinear model is less likely to be able to model the data. In such cases, the rank of a single component will be very high, and it is likely that there will be no NAR, thereby eliminating the ability to perform calibration. It has been found that MS/MS data generally fall into the first category, so that calibration of MS/MS data is possible with NBRA.

The NBRA method has been applied to two-dimensional NMR and to MS/MS data.\(^{166}\) It was found that whereas NBRA tends to have a negative bias, the quantitative results were better than those provided by a first-order technique, multiple linear regression (MLR). The NMR data were for a six-component sugar mixture, while the MS/MS data were for warfarin, \(3^-, 4^-, 5^-, 6^-, 7\)-hydroxywarfarin plus phenylbutazone. The average quantitation error over the test sets was 2.5%.

### 3.3 Multiway Partial Least Squares

PLS is a calibration technique that is widely used on first-order data. It is a method for building regression models between independent and dependent variables. Because of its success with first-order data, there has been interest in extending this technique to the calibration of second-order data.

The most obvious procedure might be to take the three-way data block, unfold it into a matrix and continue with regular PLS. However, this process has no advantage over two-way methods as far as prediction errors are concerned.\(^{167}\) A second approach that may be taken is to divide the data block into two sets, one of which is the predictor set, the other being the test set. The model being estimated by Unfold-PLS is that represented by Equation (9a–c). However, because two sets of data are used, both must be modeled as Equation (58a) and (58b):

$$r_{ijk} = \sum_{n=1}^{N} x_{in} h_{njk} + e_{r,ijk}$$ \hspace{1cm} (58a)

$$s_{ijk} = \sum_{n=1}^{N} x_{in} c_{njk} + e_{s,ijk}$$ \hspace{1cm} (58b)

where \(s_{ijk}\) is an element of the dependent variable data set, \(\mathbf{S}\), and \(r_{ijk}\) is an element of the independent variable set, \(\mathbf{R}\). The model estimates the \(x_{in}, h_{njk}\) and \(c_{njk}\) parameters such that a compromise is made between minimizing \(\sum_{i,j,k} e_{r,ijk}^2\) and \(\sum_{i,j,k} e_{s,ijk}^2\), by maximizing the covariance of \(x_i\) and a linear combination of the variables in \(\mathbf{S}\).\(^{68}\)
